Turpentine as a Disinfectant in Enuresis.—The odor of urine which follows continual enuresis can be neutralized by sprinkling a few drops of turpentine upon the sheets of the bed. While this does not wholly eradicate the smell, it produces a marked improvement.

Obituary.—Dr. A. C. Knight, at Sandusky, Ohio, September 22, aged 56—Dr. Jeremiah S. Trexler, at Kutztown, Pa., September 24, aged 69 years—Dr. John A. Peters, at Tiffin, Ohio, September 28, aged 69 years—Dr. John S. MacNutt, at Philadelphia, Pa., September 28—Dr. Aaron Cornish, at New Bedford, Conn., September 26, aged 68 years—Dr. George Singer Shiveley, at Philadelphia, Pa., September 28, aged 72 years—Dr. William Ulrich, at Waukesha, Wis., September 26, aged 83 years—Dr. R. S. Griswold, surgeon in the U. S. Army at Samar, Philippines, September 28.

GREAT BRITAIN, ETC.

The Registration of Midwives.—For some time an effort has been made in England to educate midwives, so that they could conduct a normal case of labor properly, and might know just when to call in a physician. It is now proposed to enact a law to have such qualified midwives registered and licensed, thus preventing any one else from officiating in this capacity. Public opinion seems to be totally against such a law. The people want no laws which will prevent women from obtaining the aid of friends or neighbors during labor, while, for various reasons, physicians are also opposed to the scheme. From the medical journals it seems that a long time will elapse before compulsory registration will be necessary for midwives in England.

A New Laboratory at Parel, India.—The Government of India will soon establish a large laboratory for special research work in bacteriology, under the direction of Dr. Haffkine, at Parel.

Instructions in the Pasteur Institute at Kasauli.—The Indian Government has granted permission to the medical officers throughout India to attend a special course of instruction in the bacteriology and treatment of hydrophobia at the Pasteur Institute at Kasauli.

A New Anatomical Department at Glasgow.—Lord Lister formally opened the New Anatomical Department of the University of Glasgow, on September 12th. These splendid new buildings have been provided through the munificence of the trustees of the late Mr. J. B. Thomson, the well-known shipbuilder. The new buildings include an excellent laboratory and museum, for which Professor Cleland has presented a fine collection of anatomical specimens.

Totnes Cottage Hospital, London.—Dr. William Berry Kellock has given the sum of £500 to be added to the perpetual endowment fund of the Totnes Cottage Hospital as a memorial to his late wife.

Bristol Fever Hospital.—The Corporation of the city of Bristol has finally decided to increase the accommodation at the Ham Green Fever Hospital to the extent of 62 beds at an estimated cost of £24,700.

CONTINENTAL EUROPE.

Physicians in Germany.—In the fifteen years from 1885 to 1900 the number of physicians in Germany has increased from 15,764 to 27,374.

Zurich.—Dr. Friedrich Goll, extraordinary Professor of Pharmacology, has retired at the age of 72 years. His name is familiar in connection with the posterior columns of the spinal cord. He has been succeeded by Dr. Max Cloetta, his assistant.

Fiftieth Anniversary.—Dr. Schultze, Professor of Gynecology and Obstetrics at the University of Jena, has just celebrated the completion of his fiftieth year of practice.

Plague at Naples.—Twelve cases of plague were reported last week from Naples.

The Antispitting League.—Paris has formed an Antispitting League, the object of which is to prevent expectoration in public places. The members wear a badge and publish a "Bulletin." The *British Medical Journal* fears that the purpose of the League will not be accomplished until spitting is made punishable by law. Even then it would prove difficult to have the law enforced. The force of public opinion alone will hardly be able to rid the world of spitting.

A French Physician Sentenced.—In the suburbs of Paris, a physician was recently sentenced to pay a fine of \$40 and \$200 damages, for having told the prospective mother-in-law of a patient of his that the patient was tubercular, thus bringing about a rupture of the projected marriage. Medical testimony at the trial showed that not only had he divulged a professional secret, but his diagnosis had been absolutely wrong.

Dr. Max Saenger in Poor Health.—It is with regret that we hear of the continued ill health of Dr. Max Saenger, Professor of Gynecology at the German University of Prague. Professor Saenger, who was, until two years ago, assistant to Professor Crédé, in Leipsic, is only 48 years of age. His newly erected clinic in the old Prague Hospital, which was built 111 years ago, contains 75 beds.

1.—Kleine reports 15 cases of blackwater fever, in each of which the hemoglobinuria followed, more or less immediately, the administration of quinine. He believes that the statement of Koch, that blackwater fever is due to the administration of quinine, is true. So extensive and unregulated use of quinine as in the tropics, never occurs in more temperate countries, and, therefore, we have no idea how, if at all, the prolonged administration of the drug influences the composition of the blood. In the second place, the blood corpuscles that are destroyed in blackwater fever are not healthy, but have been severely damaged by the preceding or still continuing malaria. Koch has in nowise altered his views and he is still of the opinion that, in the majority of cases, blackwater fever is the result of quinine poisoning in malarial patients. [J. M. S.]

2.—Nuttall's experiments indicate that the *Anopheles maculipennis* is attracted by some colors and repelled by others. The experiments were conducted in a large gauze tent, one end of which was formed by large windows into which the sunlight poured on bright days. Large stone basins were placed on the floor for the *anopheles* to breed in. At the beginning, it was noticed that when a person entered the tent clad in dark gray clothes the mosquitoes settled on the dark cloth, but that they never did this when the person entering was clad in white flannels. A number of boxes lined with cloth of various colors were placed in rows on the floor and it was noticed that the mosquitoes would enter the box lined with dark blue in great numbers and, in less numbers, would enter boxes lined with other colors, in the following order: dark red, brown, scarlet, black, slate gray, olive green, violet, leaf green, blue, pearl gray, pale green, light blue, ochre, white and orange. No mosquitoes were found in the box lined with yellow. As practical applications of these experiments it is to be noted that the

khaki uniform should offer advantages in addition to being invisible to the human enemy. The number of insects congregating in dwellings might very well be lessened by the choice of suitable colors applied to the walls. A trap might be made, lined with dark blue, in which the insects would congregate, so that they could be readily destroyed in large numbers. [J. M. S.]

3.—Since his first paper on the biological test for blood, Nuttall has examined 140 specimens and the results previously obtained have been confirmed. None of the bloods gave the reaction for human blood except monkey blood. The original paper appeared in the *Journal of Hygiene* for July and in the *British Medical Journal* for May 11, 1901. An abstract will be found in the *Philadelphia Medical Journal*, Vol. VII, No. 22, p. 1039. [J. M. S.]

4.—Calmette believes that a person in the incubation period of plague would find the disease considerably aggravated if he submitted to a preventive inoculation of Haffkine vaccine, and that the case would almost certainly end fatally. Haffkine, on the contrary, has all along maintained that inoculation with his vaccine is harmless in the incubation period of plague, and that that method of protection should be pushed with the utmost vigor amongst those immediately in contact with plague cases. In India, hundreds of thousands of persons have been inoculated with Haffkine plague vaccine and evidence has accumulated with sufficient accuracy to refute Calmette's statement. Bannerman publishes a table analyzing this evidence. The plague death-rate in an uninoculated Indian population varies with each epidemic, but may be put at between 75 and 85%. Of those who were actually suffering from plague at the time of inoculation the case mortality was 48.8%, which is about the same as in those who developed the disease more than 10 days subsequent to the operation. The experience of those engaged in administering the vaccine is that no harm results from the injection even in the presence of plague itself. The table referred to furnishes evidence that the prophylactic begins to act beneficially after a lapse of 24 hours only. In all cases in which the plague stricken community has been divided into an inoculated half and a non-inoculated half, it has been found that the difference in the incidence of the disease has begun to manifest itself in 24 hours. It is to be concluded, therefore, that the prophylactic has the power of aborting the disease in this stage. [J. M. S.]

5.—During the Poona plague epidemic of 1900-01, 868 patients were admitted into the General Plague Hospital who were suffering from the disease. Cortthorn aimed to make a daily examination of at least one specimen of the urine of each patient in the hospital until the disease had terminated either in death or in convalescence. It was possible, however, to report only on 597 cases. Of these, 25% of the nonfatal cases did not contain albumin, but only 7% of those that proved fatal did not contain albumin. The author thinks that the quantity of albumin is a certain guide to the gravity of the prognosis. Of the cases in which albuminuria was present, 117 persisted for from one to 7 days, and 51 from one week to two weeks. Both hyaline and granular casts were generally present, and in some cases in which the albuminuria persisted the fatty variety was also present. Plague bacilli were never found in the urine, neither by microscopic examination nor culturally. Traces of blood were found in 11 cases. 0.19% of the cases that went on to convalescence had retention; on the other hand, 12.17% of the fatal cases presented this complication. [J. M. S.]

6.—Freyer opened a discussion on stone in the tropics in the Section of Tropical Diseases of the British Medical Association. In India, stone is of the urate or the oxalate of lime variety in about 95% of all cases. Certain tracts of India are practically exempt from stone and the disease is mainly confined to the Punjab, North-western provinces and Oudh, that is, to the great alluvial plains watered by the Indus and the upper half of the Ganges. Through countless ages these rivers have carried down with them the alluvial soil that covers the plains near their origins. At the foot of the mountains, out of which these rivers flow, there is a vast continuous belt of cretaceous formation. Through ages these rivers have been changing their courses and, as a result, the plains at the foot of the mountains are supplied by water that is impregnated with lime salts in solution. These salts eventually find their way into the system through the drink-

ing water and have a tendency to be deposited in the urinary tract in the form of oxalate of lime. If this does not occur, the lime-impregnated water causing derangements of the digestive system, may lead to the formation of uric acid and urates in excess and, eventually, to deposits of crystals in the urinary passages, resulting in the formation of stone. It is a remarkable fact that the region about Hyderabad, in Sindh, where stone is more common, probably, than in any other place in the world, in addition to being covered with lime-containing alluvial deposits, lies on the most marked cretaceous formation in India. The region just described is also characterized by the scantiness of the rainfall as compared with the rest of India. It is further characterized by great alterations in temperature. These two conditions promote excessive perspiration and, thus, lead to concentration of the urine. The author believes that food plays little, if any, part in the production of stone, but believes that the drinking of lime-containing water and the meteorological conditions are responsible for the great frequency of stone in certain parts of the country. In 1899, there were 4486 operations for stone, namely, 106 suprapubic lithotomies, with a mortality of 21%; 1276 perineal lithotomies, with a mortality of 9.84%, and 3101 litholapaxies, with a mortality of 4.5%. There is nothing peculiar in the native Indian that renders him a better subject for litholapaxy than the European. The author is of the opinion that litholapaxy is the operation for stone in the bladder. Manson said that the suggestion that the distribution of stone was dependent on the presence or absence of lime in the water or on the character of the food was untenable. There are only 2 classes of calculi the etiology of which is positively known: those caused by foreign bodies introduced into the urinary tract, and those caused by the ova of bilharzia. The formation of the stone in both these instances depends on the presence of a nucleus. He believes that in other cases of stone, the etiology of which we are still in ignorance of, the explanation of the geographical distribution will be found from a study of the nucleus of the calculus. The patchy distribution of the disease in India, as well as the analogy of bilharzia calculus, suggests a parasitic cause. Simon said that he had never seen a Malay afflicted with stone and that calculi are rarely met with in the Malay Peninsula. Sandwith said that bilharzia is most prevalent in Upper and Lower Egypt, and that the ova of this parasite form a vast proportion of the nuclei of urinary calculi. Cantlie gave an account of the difficulties attending the operation of crushing stone in a tropical country. [J. M. S.]

7.—After a study of 60 cases of cerebrospinal fever, Buchanan concludes that the disease is transmitted by dust. The organism of the disease in India is the diplococcus of Weichselbaum, so that the disease is identical with that seen in Europe and America. The organism has been shown to offer considerable resistance to desiccation. Out of the 60 cases studied by the author, 57 occurred in patients who worked at occupations in which they were constantly exposed to dust, whereas only 3 occurred in patients who worked at trades that were free from dust. The incidence of the disease was greatest in the dusty months; only 4 cases occurred in the rainy season, and these developed in persons who were at work at grain cleaning, in which the amount of dust is always great. Prisoners who worked at farms of skilled labor which did not expose them to dust escaped from the disease. There were no circumstances pointing to direct contagion, and in no case were those in attendance on the sick attacked. In a hand work-shed in which 8 cases occurred in 1900, the author, this year, took steps to prevent the workmen from inhaling the dust, and not a single case of the disease occurred among the men at work in that shed. [J. M. S.]

8.—Manson's method of treating deep-seated liver abscess is to tap the abscess by a large trocar and canula, introducing a large drainage tube stretched upon a metal rod through the canula and applying siphon drainage to carry off the pus. Of 4 cases operated upon within the last year, 3 recovered and one died. These 4 cases complete a series of 28 operated upon by this method by Cantlie, of which 4 died. The author is more convinced than ever of the efficacy and safety of treating liver abscesses by the trocar and canula, and is still more ready to condemn operations by the knife. He believes that the operation should be done as soon as pus is sus-

pected and that the surgeon should not wait until the abscess has pointed on the abdominal wall or the chest wall. The histories of 4 cases are given. [J. M. S.]

9.—MacGregor opened a discussion on malaria and its prevention in the Section on Tropical Diseases of the British Medical Association. In Lagos, the prophylactic measures include the education of the natives, the administration of quinine, the use of gauze netting and attempts to exterminate the mosquito in its breeding grounds. A man that cannot or a man that will not take quinine ought not to remain in a malarious country. The usual method of the administration of quinine for prophylactic purposes is to give from $2\frac{1}{2}$ to 5 grains daily. Public dispensaries are established for the purpose of furnishing the drug to the natives. In Lagos the great objection to the use of mosquito netting is the serious and highly disagreeable way in which it checks ventilation. Muslin netting rots in the climate, but wire netting can be used for a number of years. The swamps are being filled up by convict labor in order to destroy the breeding ground of the mosquito and kerosene is also being used. The measures being taken are painfully short of what is required, but in 2 or 3 years it is hoped that the effect will begin to be felt. The habits of Europeans in the Indian stations differ in several important particulars from their habits in Indian plantations and in Africa. Particularly in relation to the use of punkahs, mosquito nets, well-built houses and comparatively good food in the Indian stations. On the other hand, these comforts are often or generally wanting in the Indian plantations and in the African coast towns; and it is just where they are wanting that the Europeans suffer most sickness. Ross has noticed that in the African coast towns the European often leads a most doleful existence. Bathed day and night in perspiration, constantly bitten by mosquitoes, without healthful exercise, cheerful society, good food or even such comforts as ice, he is not only always open to malarial infection, but also soon undergoes a marked deterioration of his body due to the incessant heat and the discomforts in which he lives. His one desire is, not to render his life more agreeable, but to escape from it on leave to England as soon as possible. It becomes more and more apparent to Ross that the use of the punkah or, at least, the electric fan, is indispensable to the European in the tropics, not only for keeping off mosquitoes, but also for preserving the general vigor of the body. Scarcely less important are the dairy, the vegetable farm, the ice-machine and the soda-water machine. All these comforts, foolishly called luxuries, are in reality absolute necessities for healthy life in the tropics. From his studies in Hong-Kong, Young concludes (1) that in every place examined, malaria was associated with Anopheles breeding pools in the immediate vicinity. (2) That in no case were Anopheles found in the neighborhood of houses without malarial fever manifesting itself repeatedly, and in every district in which malaria was found the examination of the blood of the children showed the presence of the malarial parasite. (3) That in no case was the distance from the breeding pools to the houses more than 150 yards. (4) That the breeding pools were always easily localized and comparatively easily treated by surface drainage. (5) That the only practical steps found effectual were the clearing of the district of all shrubs, grass, bamboo, etc., the driving off of the adult female mosquitoes and then draining their breeding pools. This combination is absolutely essential; to treat the pools with any larvicide alone means that the adults scatter and select other pools in which to lay their eggs. Concerning the inoculation of malaria by the Anopheles, Fearnside believes that zinc-proof houses and mosquito curtains are out of the question as preventives of the spread of malaria in India. If the mosquitoes are to be killed the rice swamps must be destroyed and, thus, the principal source of food will have to be abolished. There remain, the prophylactic use of quinine and the segregation of infected individuals. Williamson is of the opinion that there is no disease found in Cyprus, and there only, to which the name of Cyprus fever can be given; that the forms of malaria met with in the island are those least fatal; and that febricula, the other fever so frequently met with, is not dangerous to life. He urges that the term Cyprus fever be abolished. In Barbadoes, malaria does not exist, while filariasis is extremely prevalent among all classes of the community. This is explained by the fact that Anopheles mosquitoes, the definitive host

of the malarial parasite, are not found in the island, whereas *Culex fatigans*, one of the suitable intermediate hosts of *Anopheles*, abounds. Low believes that the methods adopted in other places for the extinction of the *Anopheles*, if applied in Barbadoes, would result in greatly reducing the incidence of malarial disease. Henderson thinks that the prospects of ridding the East of malaria are far from encouraging. One method of exterminating *Anopheles* which Manson thinks has not received the attention that it deserves is that of producing natural conditions inimical to that mosquito. That there are such conditions is certain, otherwise *Anopheles* would be as widely spread as *Culex*. [J. M. S.]

10.—It has long been assumed that the chief mode of ankylostoma infection is by the mouth while eating or drinking. Dirty hands, muddy feet and unwashed vegetables are daily factors in the peasant's life and are probably responsible for much of the infection. In spite of conclusive evidence that the infection takes place through the digestive tract, Sandwith believes that the skin must play an important part in admitting embryos of ankylostoma duodenale and distoma hematobium to the human body. Looss noticed that after a drop of fluid containing ankylostoma embryos had fallen on his hand there was a sensation of burning followed by redness of the skin. Later, he had an attack of ankylostomiasis. He then carefully cleaned the skin of a leg which was about to be amputated from a boy and allowed a drop of water containing ankylostoma embryos to dry on it. In an hour the leg was amputated and the skin was examined microscopically, after proper hardening and sectioning. It was found that the embryos had penetrated the hair follicles and that, so far as the drop had spread, scarcely a follicle was free. There is, of course, no proof that the embryos can work their way from the skin into the intestine, but that they can penetrate the skin seems to be proved. [J. M. S.]

11.—Duncan thinks that it is a matter of marvel that more persons are not infected with enteric fever than is at present the case in India. There is a continual supply, year by year, of a large body of men most predisposed to the disease. This body of men, though living nominally in highly sanitary barracks, are daily exposed to the infection of enteric fever contained in the liquids that they imbibe in the bazars, in the dust of the station and through the agency of the flies. The soil of India is impregnated with the bacillus of Eberth from the stools of natives who have suffered from the disease and whose sanitary regulations are, as is well known, so inefficient, and this impregnation is being added to each year, on account of the continued absence of this sanitary system in the native quarters. It is easy on these grounds to account for the causation of enteric fever in India. The author believes that compulsory inoculation for the prevention of enteric fever would serve to diminish the incidence of the disease. [J. M. S.]

12.—During a severe epidemic of plague at Patna, Maynard saw 12 cases in which there were eye complications. In all of the 12 cases the attack was severe and only 6 patients recovered with one sound eye each. In the remaining 18 eyes the cornea was hazy in 4, opaque in 2, and sloughed in 4. There were signs of iritis in 12 cases, and in 3 others the iris was prolapsed. Scleral staphylococci were met with in 2 cases. The lens was hazy in 7 eyes, and quite opaque in 5. The media were hazy in 6 cases. The fundus was normal in 3 cases; it showed a hemorrhage in one case and a limited retinitis in one other. The tension was diminished in 12 cases but was normal in the rest. The vision was fairly good in 5 cases, p. 1. in 8, and nil in 5. The notes of the cases are published.

[J. M. S.]

13.—The sick-rate of European civilian children is lower in India than it is in the United Kingdom. On the other hand, the death-rate, which in the children of soldiers in the United Kingdom is 18.31 per 1000, is 41.09 per 1000 in India. If the cases of malaria could be excluded, the health of the children of European soldiers in India would be 10% better than the health of similar children in England. The sick-rate of the children of soldiers in India is slightly in excess of that of the children of soldiers in the United Kingdom, and the excess is due to the more frequent occurrence of the eruptive fevers and respiratory diseases. The key to the higher death-rate is to be found in the debility produced by an enervating and exhausting

climate which saps the strength and renders the struggle for life so difficult in these sick children. [J. M. S.]

14.—In the Imperial Yeomanry Hospital in Pretoria there were 3 or 4 times as many medical cases as surgical. Of the medical cases the majority were diseases of the digestive apparatus, while very few were diseases of the respiratory apparatus. This would lead to the conclusion that the air in South Africa is good, while the food is bad. Washbourne believes that if the army had been provided with a proper sanitary corps, under the supervision of a good sanitary medical officer to look out for the condition of the standing camps, a large proportion of the cases of typhoid fever, dysentery and diarrhea would have been prevented. The cases of muscular rheumatism that the author saw seemed related to gout rather than to rheumatic fever. He is of the opinion that it is due to the nature of the food, especially to the absence of fresh vegetables. Although the summer temperature in South Africa is high, the author has never seen a case of heat stroke, which leads him to the conclusion that something more than the heat of the sun is necessary for the production of the condition. He inclines to the belief that heat stroke is dependent upon some infection in addition to heat. The author has failed to find the ameba coli in the stools of patients suffering from dysentery. Bacteriological examination has resulted in the isolation of streptococci and a bacillus belonging to the colon group. The death-rate from enteric fever was 9.1%; the author does not think that inoculation modifies the attack, and he doubts whether it has any influence on the incidence of the disease. In South Africa a chill is apt to be the predisposing cause of an attack of diarrhea and dysentery.

[J. M. S.]

15.—The subject for discussion in the Section of Pathology and Bacteriology of the British Medical Association was lymphadenoma. The discussion was opened by Clarke. The term lymphadenoma comprises those diseases that are characterized by overgrowth of lymphoid tissue or that give rise to growths closely resembling the lymph-nodes in structure. Lymphoid tissue may be looked upon as a specialized form of connective tissue capable of great development under irritation, and the growths of lymphadenoma partly arise from an overgrowth of pre-existing and partly in a new formation of lymphadenoid tissue. The lymphatic enlargements may be local or generalized. Apart from simple inflammatory, scrofulous and carcinomatous enlargements, the local forms may further be divided into (1) a local benign growth, which is a simple hypertrophy or is of the nature of a lymphadenitis and which may persist in the same state for years, and (2) a malignant growth, called malignant lymphadenoma or lymphosarcoma, which invades contiguous structures and may give rise to metastatic growths, but not to a generalized overgrowth of lymphoid tissue. The author believes that it is almost conclusively shown that lymphadenoma is an infective disease, occurring in both the acute and the chronic form, of which the microorganismal cause has still to be discovered. The fact that tubercle may produce a disease almost exactly simulating lymphadenoma is a corroboration of this view. Although a certain number of cases described under lymphadenoma or Hodgkin's disease are in reality tuberculosis, there is no warrant for the view maintained by some writers that the disease is merely a general lymphatic tuberculosis. It would conduce to clearness to confine the term lymphosarcoma to tumors limited to one or more groups of lymph glands in contiguity, varying in rate of growth, perforating the gland capsule, infiltrating or invading the surrounding tissues, sometimes causing metastases in distant organs, but without general involvement of the lymphatic tissues and composed of small round cells with a fine reticulum. In the past, the 2 conditions of lymphadenoma and lymphatic leukemia have sometimes been taken one for the other; but in the latter condition, though the glandular enlargements resemble lymphadenoma, there are also greatly enlarged spleen and a leukemic condition of the blood, so that the 2 diseases are distinct. In children there is some difficulty in distinguishing lymphadenoma from anemia infantum pseudoleukemia, but the latter is a separate disease. In certain rare cases of lymphadenoma there may be great enlargement or persistence of the thymus gland. Again, there is a curious condition known as status lymphaticus or lymphatism in which there is partial or general hyperplasia of lymphatic glands

In which the patients are liable to very sudden death from trifling causes. The disease presents numerous points of similarity to lymphadenoma, but as yet there is not sufficient evidence to determine the relationship. Bryant reports a case in which, clinically, there was no doubt about the diagnosis of lymphadenoma. At the autopsy, however, there were such marked fibroid changes in the parts involved and the organs presented such unusual appearances that the question of some other condition arose. When the specimens were examined microscopically the doubt was increased and the possibility of syphilis arose. Without coming to a conclusion regarding the relationship between lymphadenoma, syphilis and fibrosis, the author is of the opinion that the case reported by him must have had some influence, such as alcoholism or syphilis, added to the lymphadenoma in order to explain the pathological changes. Gulland said that the 4 conditions that are likely to be confounded are leukocythemia, lymphosarcoma, generalized tuberculosis of the lymph-nodes and true lymphadenoma, if such a condition exists. Leukocythemia ought to be diagnosed definitely by examination of the blood. Lymphosarcoma is a rare condition and generally starts in the lymphatic apparatus associated with the alimentary tract or the respiratory tract. The immense majority of cases clinically diagnosed as lymphadenoma are really generalized tuberculosis of the lymph-nodes. No case should be pronounced non-tuberculous unless none of the numerous glands examined contain tubercle bacilli, and are found not to produce tuberculosis on inoculation into the lower animals. The author is very doubtful of the existence of true lymphadenoma. Stiles is very sceptical as to the existence of lymphadenoma, although in the past 2 years he had operated on 4 cases of extensive lymphomatous swelling in the neck that were not tuberculous. He is of the opinion that more than one organism is responsible for such conditions of the lymph-nodes and he believes that the streptococcus is one of them. Longridge suggested that if tuberculin was injected into a patient suffering from supposed lymphadenoma the tuberculous nature of the affection could be demonstrated.

[J. M. S.]

16.—Symes describes a method of collecting blood for bacteriological examination. He has found that fluid media are more satisfactory for bacteriological examination of the blood than solid media. This is possibly because the fluid media serve as a diluent of the bactericidal power of the blood, while on solid media this power remains unchanged. Occasionally, although no colonies are to be found on the surface of the medium, colonies will be found in the clots that form in the bottom of the tube. Out of 12 cases of septic infection, organisms were found in the blood in 4. One was a case of puerperal sepsis, in which the staphylococcus pyogenes albus was found; the second was a case of puerperal sepsis in which the same organism was found; the third was a case of pyemia following a wound of the foot in which a streptococcus and the staphylococcus pyogenes albus were found, and the fourth was a case of septicemia following a wound in which the micrococcus tetragenus was found. Out of 7 cases of acute infective endocarditis microorganisms were found in the blood of 3. The offending organism in one case was a streptococcus and in the other 2 cases was the staphylococcus pyogenes albus. Out of 3 cases of pneumonia the pneumococcus was found in the blood of one and the staphylococcus pyogenes aureus, together with a streptococcus, in another, the third blood was sterile. The total number of cases examined was 31, of which 9 presented microorganisms. For the purposes of diagnosis, then, the bacteriological examination of the blood is seldom of real practical value. If, on the other hand, organisms are found in the blood, the treatment indicated would be the proper antiserum; although the failure to detect an organism should not be considered an indication for withholding the antiserum. All observers agree that the discovery of organisms in the blood renders the prognosis of the case exceedingly grave. [J. M. S.]

17.—Douglas has found that in the cells of the anterior cornu of the spinal cord the chromophilous granules are aggregated into definite masses which are uniformly distributed throughout the cell protoplasm. In the cells of the column of Clarke, on the other hand, the Nissl bodies, as these aggregations of the chromophilous granules are called, have a more or less peripheral distribution.

[J. M. S.]

LANCET.

September 14, 1901.

1. Presidential Address on the Range of Physical Theories. ALTHUR W. RUECKER.
2. On the Changes Effected by Anti-Typhoid Inoculation in the Bactericidal Power of the Blood, etc. A. E. WRIGHT.
3. Tubal Gestation Sac Entirely Anterior to the Uterus; Operation; Recovery. ALBAN H. G. DORAN.
4. The Post Office and the Prevention of Tuberculosis. CHARLES H. GARLAND.
5. Some Points in the Pathology of Pernicious Anemia. WILLIAM BAIN.

2.—Wright presents an article "on the changes effected by anti-typhoid inoculation in the bactericidal power of the blood; with remarks on the probable significance of these changes." Three previous communications have been published in the *Lancet*; one on December 1, 1900, the second on March 2, 1901, and third on June 1, 1901. In these previous articles, he outlines the methods (A) for determining the desired dilution of a bacterial culture; (B) methods for mixing volumes of serum with corresponding volumes of successive dilutions of bacterial cultures in a series of capillary tubes; (C) the technic for testing the bactericidal effect upon these dilutions produced by serum, and finally he gives methods for enumerating the living bacteria contained in the culture. In the present communication, the author has carried on a series of investigations upon individuals and these were in each case made upon surgeons-on-probation in attendance on the Army Medical School, Netley. The anti-typhoid inoculations which consisted of sterilized culture, were in all instances begun with very small doses. Only from one-third to one-half of the dose required in the case of a soldier was used. Almost invariably the primary inoculations were not followed by the local and constitutional disturbances so commonly seen after anti-typhoid inoculation. The determinations of the bactericidal power of the blood were made before and subsequent to anti-typhoid inoculation. The results of these observations are set forth in three tables. In the first table, the results of the experiments relate to fourteen surgeons-on-probation who had never suffered from enteric fever. These individuals were inoculated with fresh typhoid vaccine. The second table includes the data of the experiments made on two surgeons-on-probation who recently convalesced from enteric fever. These persons were also inoculated with fresh anti-typhoid vaccine. The third table represents the results of observations made on four surgeons-on-probation who had not suffered from typhoid fever, and who were inoculated with typhoid vaccine prepared respectively 18 and 24 months previous to the time of experimentation. Definite evidence of bactericidal effect upon the bacillus typhosus by the blood of the individuals was obtained in 13 out of 14 normal persons, in one out of two convalescents of typhoid, and in two out of four normal persons inoculated with the old vaccine. The positive phase of increased bactericidal power of the blood manifested itself within an extraordinarily short period. A considerable number of days were required for a full development of the bactericidal power. A summary of these observations is deduced, which we give in substance:—"With regard to the sequence of events after an anti-typhoid inoculation it has been shown: 1. That where the quantum of anti-typhoid vaccine employed produces the familiar well-marked constitutional symptoms, a decrease in the bactericidal power of the blood and a correspondingly increased susceptibility to typhoid infection may supervene in the period immediately subsequent to inoculation. Upon this negative phase of increased susceptibility there may, however, be expected to succeed, probably within a period of three weeks or less, a phase of increased bactericidal power and a greater resistance to typhoid. 2. That when the quantum of anti-typhoid vaccine employed produces very severe constitutional

symptoms, a negative phase of increased susceptibility will be produced, which—and the same would appear to hold true also in the case of a negative phase supervening upon an actual attack of typhoid fever—may never be followed up by a positive phase of increased resistance. 3. That when the quantum of anti-typhoid vaccine employed is reduced to the point at which marked constitutional disturbance is avoided, a positive phase of increased resistance may be expected to supervene without the intervention of any negative phase, and in many cases within 24 hours." Some practical conclusions are also drawn. In these he emphasizes the value of anti-typhoid inoculation, and the importance of using very small doses in the presence of an epidemic, so as to avoid marked constitutional disturbance. In the absence of an epidemic of enteric fever, larger doses may be employed. [F. J. K.]

3.—Doran remarks that in tubal gestation the sac of the earlier months of pregnancy nearly always fills Douglas's pouch and more or less of the lateral fornix on the side where it develops. Thus, when the other symptoms of extrauterine pregnancy are present, a swelling to the left of the cervix usually signifies that the left tube is the seat of gestation. Experience has shown, however, that a tubal sac may be displaced so as to lie on the opposite side of the pelvis. Still, whether the tubal sac lies on its own side or crosses the pelvis, it almost invariably occupies Douglas's pouch, that is to say, it lies behind the uterus. Doran now describes a case in which the gestation-sac rested entirely anterior to the uterus. The patient was operated upon successfully. An interesting feature of the case was an adhesion of the vermiform appendix to the gestation-sac.

[W. A. N. D.]

4.—Garland writes on the post-office and the prevention of tuberculosis. This author directs attention to the fact that the methods adopted for the disinfection of post-offices have been so well carried out that contagious diseases, except tuberculosis, are rare among the huge staff of employees. He points out that the official figures for the whole staff show that the mortality from tuberculosis is relatively and absolutely high. The author has appended a table illustrating the loss from phthisis during the years 1896, 1897, 1898, and 1899. These statistics show the death rate of the whole postal staff to be higher than that of the general population during the years mentioned above. He believes that it is the duty of the State to direct the way in the adoption of preventive measures, for at the present time there are practically no measures used to prevent tuberculosis in the post-office. Reference is made to the precautionary measures which have been adopted in the French postal and telegraph departments. [F. J. K.]

5.—Bains reviews some points in the pathology of pernicious anemia. Reference is made to the view held by Hunter, who believes that the toxin of a special micro-organism in the intestinal canal is absorbed, and is responsible for excessive hemolysis in the portal area. The liberated blood pigment is excreted in the urine and in the bile, while the free iron is stored in the spleen, liver, and other organs. Stockman maintains that pernicious anemia is not a disease *per se*, but a condition which supervenes on an ordinary severe anemia accompanied by vascular degenerative changes, followed by capillary hemorrhages. Mott is inclined to the view that pernicious anemia is essentially a disease in which there is excessive activity of the blood destroying function of the liver and spleen. The following report of a case is given: A man, 36 years of age, was admitted to the Leed's Infirmary on September 24, 1901. He had been for four years a sufferer of pernicious anemia. The disease began insidiously; gradual weakness set in, he lost his appetite, and the skin assumed a yellowish tinge. A year after the onset of the illness, the patient noticed blood and mucus in the feces, and also complained of nausea, and occasional vomiting after taking food. As the disease progressed, the weakness became more pronounced, and palpitation and dyspnea set in. An examination showed the following: The patient's skin presented a dirty yellow tinge. He was extremely weak, his tongue was pale and uncoated, the bowels constipated, and his

appetite poor. His teeth were in a bad condition. In the right hypochondriac region, there was slight fullness, and the spleen was enlarged. At the base of the heart and at the apex a systolic murmur was audible. The retina was the seat of hemorrhages. The following blood counts were made: September 26th, the red cells numbered 970,000 per cubic millimetre; the hemoglobin percentage was not determined. There was no leukocytosis. On September 29th the red cells numbered 880,000 per cubic millimetre. On October 20th, red cells 2,100,000 and on November 22nd the colored corpuscles numbered 3,240,000; the hemoglobin 72%. The patient gradually improved from the time of admission on a treatment consisting of Hommel's hematogen, arsenic, and oxygen inhalation. The following case of chlorosis is also reported: On January 17, 1901, a domestic servant, 22 years of age, was admitted to the Leed's Infirmary, suffering from gastric ulcer and chlorosis. The symptoms were pain and vomiting after taking food, shortness of breath, palpitation, and edema of the extremities. A loud systolic murmur was heard at the apex, which was transmitted towards the axilla. The author has inserted in his article a table which illustrates an analysis of 24 hour collections of urine in cases of pernicious anemia and chlorosis, respectively. This table points out a comparison of the quantity of urine and the specific gravity, the amount of urea, the acidity, the amount of uric and phosphoric acids, preformed sulphates and conjugated sulphates. A number of determinations were also made in regard to urobilin, indican, hematoporphyrin, and skatoxyl sulphuric acids. This table shows that the uric acid excretion in pernicious anemia is below the normal average, while in chlorosis it is normal. The conjugated sulphates are relatively increased in pernicious anemia and there was also an increase in the formation of indican, skatoxyl sulphuric acid, and urobilin. The author is of the opinion that Hunter's theory is the correct one, although he states that his arguments are not absolutely conclusive. Bains maintains that the liver should be accorded precedence over the spleen as a hemolytic organ. In regard to the cause of this hemolysis, it must be said that this remains an unsolved problem. It appears quite certain that the excessive hemolysis occurs within the portal system, for there is no hemoglobinuria, and consequently no free hemoglobin in the general circulation. [F. J. K.]

MEDICAL RECORD.

September 28, 1901.

1. A Matter of Interest in Blood Structure Study. WOODBRIDGE HALL, BIRCHMORE.
2. Report of a Case of Intracranial Tumor; Operation; Recovery. WM. M. LESZYNSKI.
3. Operative Procedure for Tumor of the Brain. JAMES H. GLASS.
4. The Prophylaxis of Tuberculosis. JOSEPH KUCHER.
5. The Home Management of Epilepsy. R. H. PORTER.
6. The Origin of Retroversion of Uterus and Its Pathological Dignity. SAMUEL W. BANDLER.
7. Treatment of Typhoid Fever. BASIL M. TAYLOR.

1.—W. H. Birchmore presents a paper on a matter of interest in blood structure study. Four drawings are included in the article. The spreads were made from blood, still fluid, which had been effused into the great lymph spaces between the deep muscles of the neck of a turkey, consequent upon the cutting of the carotid artery by way of the mouth. The unusual condition of the nuclei of the red corpuscles attracted attention. The nuclei in the blood cells of domestic fowls are evacuated from many cells and are present within the cells of many more. In these specimens the nuclei were not extended for the most part. The author has made a critical study of the morphology of the corpuscles observed. An interesting feature of the examined blood was a fact that it did not coagulate and that the changes described seemed to be changes of development. [T. L. C.]

2 and 3.—William M. Leszynski and James H. Glass report a case of intracranial tumor with operation and recovery. The symptoms were a right neurorhinitis and a left receding papillitis. There were no aphasic symptoms. There was paresis affecting all extensor muscles and the shoulder girdle of the left upper extremity. The right was normal.

There was no static ataxia. In walking the patient dragged the left leg and was unable to stand on the left leg alone. The flexors were partially paralyzed, and there was also some paresis of the extensors. There was no muscular rigidity. The left knee-jerk and the Achilles reflex were exaggerated, but there was no ankle clonus. Urine negative. The diagnosis of an intracranial tumor of slow growth involving the arm and leg centers in the cortex of the right hemisphere was made. During the operation profuse hemorrhage was encountered and it was necessary to overcast all soft tissues and plug with bits of bone the nutrient canals of the cranium. The vessels of the exposed dura were engorged with blood, and were ligated before this membrane was incised, which done, revealed almost centrally located in its relation to the opening, the convex surface of the growth pushing out above the surface of the brain. The tumor was enucleated up to the longitudinal sinus, to which it was attached through the falx cerebri, and from this membrane it was carefully dissected off. In shape the tumor was spherical and about 20 mm. in diameter. To control the oozing the wound was packed with strips of gauze tape, the ends of which were brought out through drill holes in the angles of the wound, after the replacement of the osteoplastic flap, which was secured with silver wire. The patient made a good recovery.

[T. L. C.]

4.—Joseph Kucher discusses the prophylaxis of tuberculosis. There is no better and surer way to prevent consumption than to keep away from the danger of infection. It can be done by avoiding the causes which make the human body susceptible to it. Living, working and sleeping in a confined and contaminated air are the foremost of these. Out of all the United States, only fourteen have laws relating to inspection of factories and workshops. Among the contributing causes are certain occupations such as those of silex cutters, needle-sharpeners, file cutters and lithographers, etc. Prolonged worry, excess and dissipation are important factors. [T. L. C.]

5.—R. S. Porter discusses the home management of epilepsy. The patient, as a rule, is not competent to take care of himself. An attendant who can be trusted should oversee the administration of medicine and follow out the physician's instructions. To apply these principles to the daily life of an epileptic, often requires great patience, forbearance and self-denial, and yet much can be done when these are shown. There are few or no rigid restrictions in regard to the diet. Prudence and temperance in all things should be carefully followed. Stimulants are to be avoided, and the emotions, such as excitement, worry, etc., must be controlled. [T. L. C.]

6.—Bandler describes the condition of *retroversioflexio uteri*, and mentions as associated symptoms dysmenorrhea, sterility, metritis, endometritis, oöphoritis, and bladder, rectal and nervous symptoms. He gives as the probable origin of the condition relaxation of the ligaments and loss of elasticity of the levator ani muscle. In order to explain the congenital cases he enters largely into a study of embryology. He decides that congenital retrodeviations are very frequent, and that *retroversioflexio* constitutes a practically normal condition. Congenital *retroversioflexio*, he claims, is not frequently followed by hysterectomies. This disease is not an obstacle to the cure of pelvic affection, and if accompanied by severe local symptoms, these may be corrected in a vast majority of cases without surgical treatment. [W. A. N. D.]

7.—B. M. Taylor contributes a paper on the treatment of typhoid fever. He divides his patients into two classes: First, those who have been healthy prior to the acute disease; second, those who have had some chronic disease for years. The digestion must be watched with especial care, and if there is myasthenia with fermentation, give a small amount of food, easily digested and slow to ferment. The white of an egg given raw with pepsin and hydrochloric acid suits these patients. Do not give milk to patients with gastric catarrh or myasthenia; milk given every three or four hours will kill more patients than the fever. Treat the stomach and feed it as if it was the only trouble the patient had. The motto is: "To remember the stomach first, the colon next." He bathes the patient in tepid water for about 20 minutes, and emphasizes the necessity of avoiding disturbing the patient during his sleep and the value of prolonged and absolute rest. [T. L. C.]

MEDICAL NEWS.

September 28, 1901. (Vol. LXXIX, No. 13).

1. A Contribution to the Surgical Relief of Cancer of the Rectum; Revision of the Statistics to Date, with Special Reference to Sacral Extirpation. FRANK LE MOYNE HUPP.
2. The Problems of Physiology and Pathology. MARTIN H. FISCHER.
3. Intratracheal Injections in Bronchial and Pulmonary Affections. WILLIS S. ANDERSON.
4. Presbyopia; Accommodation; Astigmatism. NORBURN B. JENKINS.

1.—Hupp gives an interesting résumé of the history of the surgery of the rectum for cancer, especially dwelling on the more recent method of sacral extirpation. He remarks that it was not long ago that the entire subject was dismissed from the text-books with the advice to treat the symptoms and relieve pain as long as possible, and a final resource to colotomy. Kraske's method of sacral resection has been adopted largely and has been very considerably modified by various surgeons, including Bardenheuer, Heinecke, Kocher, Levy, Hegar, Hochenegg, and Lange. Hupp reports a number of operations in his own experience and revises the statistics up to date. There are now 761 sacral operations for cancer of the rectum reported from Germany, Austria, and Switzerland, with a few in the British Isles, giving an operative mortality of about 18%. [W. A. N. D.]

2.—In *The Problems of Physiology and Pathology*, M. H. Fischer explains the heart beat as follows: The puzzle of the heart beat has been brought a step nearer solution. It has been definitely proved that the rhythmic activity of the heart is dependent upon the presence of certain salts in the blood. The heart cannot beat except in the presence of sodium ions in the circulation, but sodium ions alone act as a poison and soon bring the heart to a standstill. The presence of certain other, for example, calcium ions, however, neutralizes the poisonous effects of the sodium ions. Indeed in a mixture of these two salts the heart muscle will beat rhythmically for hours. Any of the voluntary muscles can be made to contract rhythmically just as the heart muscle by the simple abstraction of a little calcium from the mixture of these salts. It is a slight excess of calcium in our blood that keeps the voluntary muscles from contracting rhythmically. These facts are interesting in another direction; they show that in this case chemical and not morphological differences underlie variations in function. In the physiology of taste, the theory of ionization has also correlated many heterogeneous facts. Acids taste sour because they contain hydrogen ions; the characteristic taste of hydroxides is due to their hydroxyl ions. With inorganic compounds the intensity of the taste is directly proportional to the number of ions that the solution contains. With organic salts, however, this law does not hold. The halogens have a salty taste due to the halogen ions. Sodium, potassium, magnesium, lithium and other metallic ions each have an individual taste. Thus the taste of a given salt is dependent upon the nature of the ions that constitute its molecule. [T. M. T.]

3.—W. S. Anderson, in *Intratracheal Injection in Bronchial and Pulmonary Affections*, concludes as follows: (1) It is of no advantage in acute bronchitis, at least during the congestive stage; (2) It is of distinct advantage in subacute and chronic bronchitis; (3) It is of positive benefit in bronchiectasis; (4) It is valuable in pulmonary tuberculosis, relieving many of the symptoms, especially those due to secondary infection; (5) It quickly relieves the distressing symptoms of asthma. The amount of relief and the permanency depend largely upon the predisposing and exciting causes; (6) It in no way interferes with other lines of treatment; (7) The writer has never seen harm follow its use, although in a very few instances it excited severe coughing for a short time. [T. M. T.]

4.—N. B. Jenkins states that in youth the focusing muscle can so mold the soft crystalline lens that fine print is distinct as near as three or four inches to the eye. As age advances the lens hardens and decreases the active focusing power until fine print, such as foot-notes, can no longer be read at the proper reading distance. This condition is presbyopia. The active focusing power gradually decreases until about the seventieth year, when the focusing muscle loses nearly all power over the hardened lens, and at this age the perfect eye needs for reading a magnal-

ner equal in strength to what the active focusing power was just before presbyopia came on. Until the fiftieth year most people with farsighted, near-sighted and astigmatic eyes can read fine print with glasses which totally correct these imperfections. Many at fifty-five years of age and some at sixty can do this. Many with normal distant vision at fifty to sixty years of age have never used reading glasses, and yet are a trifle farsighted or astigmatic. Presbyopia does not come at the fortieth year. Those who need glasses this early have farsightedness, nearsightedness or astigmatism. Belladonna is not used in testing the eyes of the aged, so the focusing muscle may mask imperfections after the fortieth year almost as much as earlier. Latent imperfections may exist until the sixty-fifth year. [T. M. T.]

THE NEW YORK MEDICAL JOURNAL.

September 28, 1901.

1. The Lane Lectures on the Social Aspects of Dermatology. MALCOLM MORRIS.
2. The Gonococcus and Its Toxin. J. RILUS EASTMAN.
3. A Study of the Temperature, Pulse and Respiration in the Diagnosis and Prognosis of Certain Diseases of the Brain. J. T. ESKRIDGE.
4. Two Cases of Intestinal Obstruction Diagnosed by the X-Rays. J. RUDISJICINSKY.
5. The Abstraction of Calcium Salts from the Mother by the Fetus a Cause of Osteomalacia in the Former. JENNIE G. DRENNAN.

3.—J. T. Eskridge concludes his article on A Study of the Temperature, Pulse and Respiration in the Diagnosis of Certain Diseases of the Brain as follows: (1) By a careful study of the temperature, pulse and respiration much valuable information that will aid us in the diagnosis and prognosis in certain diseases of the brain can be obtained; (2) Much care must be exercised and considerable time and patience are required on the part of the physician in obtaining reliable records; (3) Nurses are totally incompetent for such detailed work, unless they have been specially drilled for it; (4) A change in the character of the respiration, rather than in its frequency, is sometimes one of the first positive symptoms of organic intracranial disease, especially of tuberculous meningitis; (5) A respiration that is more frequent while the patient is asleep or unconscious than it is during the waking or conscious moments is very strong evidence of organic disease so situated as to interfere with the respiratory centers; (6) Apoplexy due to hemorrhage is attended with greater disturbance of the temperature of the body soon after the occurrence of the stroke than is the case, when the apoplexy is due to thrombus or embolus. The temperature disturbances in apoplexy due to hemorrhage, especially if attended with hemiplegia, are a slight fall of the axillary heat within an hour or less after the occurrence of the hemorrhage, the fall being a little greater on the paralyzed side; after reaction has occurred (eight or twelve hours on the average) a slight rise of temperature, a little greater on the paralyzed than on the opposite side; an elevation of temperature from half to 2° or 3° above normal for the next few days, the temperature remaining a little higher on the paralyzed than on the unaffected side for a week or more (in cases of complete hemiplegia); later the temperature slightly lower on the paralyzed side if trophic disturbances occur; (7) In apoplexy from thrombus or embolus there is scarcely an appreciable disturbance of temperature before the end of the second day, except in the severer cases. In these cases it is slight. In the majority of cases of apoplexy from thrombi or emboli there is no marked variation of temperature from the normal at any time, so that disturbance of the temperature on the first day points very strongly to hemorrhage as the cause; (8) Considerable disturbance of temperature, beginning from the second to the fourth day, is significant of thrombus or embolus, and indicates extensive softening and an unfavorable prognosis; (9) If the temperature on the paralyzed side remains higher than on the opposite side several weeks after the occurrence of the apoplexy from any cause, it indicates that softening or inflammation of the brain is going on, and lends great gravity to the prognosis; (10) It is premature to arrive at any definite conclusions from a study of the temperature, pulse and respiration in traumatism of the brain. This class of cases on account of their great importance, deserves a

more detailed study of all the symptoms. It is probable that if cases of traumatism of the brain were classified and grouped according to the severity of the injuries and the character of the symptoms, a careful comparison of the temperature, pulse and respiration would lead to important conclusions. The author also makes the following statements in regard to the traumatic class of cases: (a) All cases of injuries to the head in which the temperature does not reach normal or slightly above a few hours after the receipt of the traumata will probably prove rapidly fatal. The higher the temperature, the greater the probability, that contusion of the brain and membranes is a more important factor in the case than intracranial hemorrhage. The greater the variation of the temperature from normal, either above or below, the worse the prognosis; (b) A rapid, weak, and intermittent or irregular pulse denotes great danger. A pulse that is at first slow, but soon after becomes quite rapid, indicates that the brain power is being overwhelmed by the intracranial lesion and justifies a bad prognosis; (c) An exceedingly slow (8 or 10 to the minute) and intermittent respiration indicates a lesion at the base, in the posterior fossa. The slower and the more pronounced the intermission of the respiration the greater is the danger of sudden death. A respiration at first nearly normal in frequency, but soon after becoming quite rapid, indicates a rapidly fatal case. [T. M. T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

September 26, 1901.

1. Problems in Medical Education. HERBERT L. BURRELL.
 2. Observations on Heart Disease. ROBERT T. EDES.
 3. The Pupil in General Disease. EDWIN E. JACK.
 4. Report of Cases from the Second Surgical Service of the Children's Hospital, Boston. H. L. BURRELL, R. W. LOVETT and J. E. GOLDTHWAIT.
 5. Spermine Crystals in Pus. EDWARD T. WILLIAMS.
- 2.—The exact diagnosis of the condition of the heart muscle is not easy but its importance has not been undervalued. Even if absolute precision is unattainable, an estimate of the relations between the amount of work to be done and the power of the heart to do it, may be made to an extent sufficient for purposes of prognosis and therapeutics. The variations in the load which the heart has to work under arise to some extent from the mass of blood but much more from the demands upon the voluntary muscular system for its supply of oxygenated blood and upon the resistance offered to its distribution. The observation of the pulse, of the venous circulation, of localized congestion and edema is the real guide as to the efficiency of the heart's action. The sphygmograph is probably inferior in some respects, beside that of convenience, to the trained finger. Edes is of the opinion that the fingers should determine the size and degree of elasticity of the artery, the extent to which it is filled by each beat of the heart, how long the blood is retained without running back through the aortic valves, how rapidly it escapes from the arteries and how much pressure is required to extinguish the pulse. It may not be possible from any combination of symptoms to diagnose actual degeneration of the cardiac muscle with absolute certainty, but under many circumstances this diagnosis may be made with sufficient probability for practical purposes. The suggestion made by Jacobl, that the difference between the cases of fatty degeneration with a slow pulse, of which there are some, and those with quick ones, of which there are more, consists in the involvement of the cardiac ganglia in the same process that affects the muscle and very frequently the coronaries in both, is a very plausible one and has some clinical evidence in its favor. It does not rest, however, on an assured anatomical basis as yet.

[J. M. S.]

3.—In testing for the light reflex the eyes should be tested one at a time and should look at a distance of 20 feet or more into darkness or at some object. The source of light should be in front and slightly to one side. Direct daylight may be used. There is no absolute normal standard for the size of the pupil. In diagnosing the situation or nature of an intracranial lesion the pupillary symptoms are of little significance if they exist alone, except that the lesion must affect the nucleus itself or be peripheral. If, however, with this isolated symptom there are

those of the involvement of other branches or nerves, the importance may become considerable. [J. M. S.]

4.—Burrell reports the case of a girl baby, aged three days, who was operated upon for imperforate rectum. The patient recovered. Lovett reports the case of acute arthritis of the hip joint, with dislocation of the femur in a girl, aged 11 months. The dislocation was reduced by the open method. Goldthwait reports a case of dislocation of the hip occurring during an acute inflammatory process, which was probably rheumatic, in a girl, aged 8 years. The dislocation was reduced and a normal joint existed at the end of the treatment. [J. M. S.]

5.—Williams examined the pus from a cervical abscess of several months duration. The pus was thick, curdy and slightly mixed with blood. He added 8 parts of salt solution to the 1000 of pus and set it aside for 2 days. At the end of that time the supernatant liquid was decanted and a considerable proportion of a saturated solution of neutral ammonium phosphate was added to it. This was set aside for another day when the precipitate was examined microscopically and found to contain spermine crystals.

[J. M. S.]

FRANK P. NORBURY.

1.—Weir considers the Kraske operation unsatisfactory for the removal of high seated cancers of the rectum. The wound is deep, it is difficult to draw down the upper portion of the bowel, and troublesome to suture the anal portion to the proximal end. The author proposes a modification of the Maunsell method. The abdomen is opened, the bowel separated nearly to the tip of the coccyx and in front to the edge of the prostate. Two iodoform tapes are tied around the bowel about three inches from the anus and the intestine severed between them. The lower end of the rectum is then inverted and drawn out through the anus by a pair of forceps. The growth is resected and the lower end of the upper segment drawn down through the dilated anus and the edges of the two segments united. After the peritoneum is sewn together and to the bowel, so that the pelvis and general cavity are separated, drainage from the peri-intestinal space is provided for by a tube just in front of the coccyx. Three patients have been operated upon by this method; two recovered and one died from a persistent diarrhea. [F. T. S.]

2.—Senn says, searching criticisms have shown almost conclusively that the so-called cancer bodies are not living organisms but the products of degeneration of cell protoplasm of cell inclusions of a parasitic nature. He defines carcinoma as an atypical proliferation of epithelial cells from a matrix of embryonic cells of congenital or post-natal origin. The histology and histogenesis of carcinoma speak against its parasitic origin. The increase of carcinoma is more apparent than real. The positive results of implantation and inoculation experiments have failed to establish beyond all doubt the parasitic theory of carcinoma. Two great objections are the variety of microbes and bodies which have been made, have been in operative treatment. The histology and histogenesis of carcinoma does not correspond with the structure of true carcinoma. The author has inoculated himself with carcinoma some five months ago. A month later the graft had disappeared, leaving no evidence of a scar. The only real advances which have been made, have been in the operative treatment. Medicines, injections, local applications, and the serum treatment have but a limited application. The early and radical operative treatment offers the only prospect

of cure, the permanency of which cannot be determined in less than ten years. [F. T. S.]

3.—Futcher communicated an article to the Section on Practice of Medicine of the American Medical Association, at its fifty-second annual meeting, on "cirrhosis with pigmentation." The author states that 49 cases of atrophic cirrhosis of the liver (Laennec's) have been treated in the wards of the Johns Hopkins Hospital, and in this service not a single instance of permanent pigmentation had been observed. Eight cases of hypertrophic cirrhosis of the liver were also studied and one of these presented bronzing of the skin. The author reviews the literature of cases of cirrhosis of the liver with bronzing of the skin. In regard to the symptoms of this condition, he refers to the clinical analysis made by Anschütz who studied 24 cases collected from the literature up to 1899. The symptoms are those of rapidly fatal diabetes mellitus accompanied with cirrhosis of the liver, commonly of the hypertrophic variety. The pigmented cirrhotic liver is found at autopsy. This pathological manifestation was found in 23 out of 24 of Anschütz's cases, in all but one instance the liver was enlarged. It contained an ochre colored, iron-containing pigment. This pigment was present in the liver cells and in the connective tissue. In fifteen of the cases, there was also a marked increase in the amount of the connective tissue of the pancreas, and eighteen of the cases revealed pigmentation of the pancreatic epithelium and connective tissue. Futcher states that the pigment of the liver is now generally believed to be the exciting cause of the liver changes. Reference is made to the work of Opie, who has designated this pigmentation of the liver and pancreas as a distinct pathological entity, and he believes that the term hemochromatosis should be used to designate this condition. In regard to hemochromatosis, the author quotes the conclusions which Opie has drawn. They are as follows: "(1) There exists a distinct morbid entity, hemochromatosis, characterized by the widespread deposition of an iron-containing pigment in certain cells, and an associated formation of iron-free pigments in a variety of localities in which pigment is found in moderate amount under physiologic conditions. (2) With the pigment accumulation there is a degeneration and death of the containing cells and the consequent interstitial inflammation, notably of the liver and pancreas, which become the seat of inflammatory changes, accompanied by hypertrophy of the organ. (3) When the chronic interstitial pancreatitis has reached a certain grade of intensity, diabetes ensues and is the terminal event in the disease." The article is concluded with the report of a case which occurred in a male 50 years of age. The skin of this patient, particularly that of the hands, wrist, and the legs, was deeply bronzed. The liver was markedly enlarged, and the urine did not contain albumin or sugar, but gave a reaction for indican and iron. [F. J. K.]

4.—Stockton discussed "circulatory disturbances accompany hepatic cirrhosis" before the Section on Practice of Medicine at the annual meeting of the American Medical Association. In his article, he describes the relation of the portal to the general circulation, and the circulatory disturbances that occur with atrophic cirrhosis. He gives a report of a number of cases. He concludes that when the portal blood enters the general circulation without having passed through the liver, a toxemia is produced. This portal blood escapes into the general circulation when the blood pressure in the portal vein is raised. The toxemia which occurs from the escaped portal blood in the general circulation is more marked when the blood pressure in the portal vein is suddenly raised. When the increase in the blood tension in the portal vein is gradual, the toxemia is less marked. Purgation tends to relieve the increased blood tension in the portal vein and therefore lessens the toxemia. [F. J. K.]

5.—Pusey discusses the "Roentgen Rays in the treatment of diseases of the skin." He outlines the value of the X-rays for the removal of superfluous hair. The author has had nine cases of this kind under his observation. The treatment by the X-rays produced partial or complete alopecia in seven out of nine instances. The fact that the X-rays have an effect on the subcutaneous and sweat glands, suggests the possible value in the treatment of disorders of these glands, acne and hyperidrosis. The favorable influence of the X-rays in the treatment of tinea tonsurans, favus, and sycosis is also mentioned. He states

that the X-rays have been highly recommended in the treatment of eczema, lupus vulgaris, and carcinoma.

[F. J. K.]

6.—Jepson reports "a case of unilateral cystic kidney" in a child 11 months and 14 days old. The points of interest in this case are the following: The condition involved only one kidney and in its development it did not lead to serious disturbances until pressure was exerted upon the gastro-intestinal tract. The probable diagnosis of this condition was made by a very careful examination. An operation was performed under chloroform anesthesia, which lasted but 14 minutes. The cystic kidney was removed and a rapid recovery followed. The author emphasizes that this case illustrates the capability of children to endure operations provided that the precaution of giving a minimum amount of anesthetic is exercised and reducing the blood loss to a minimum. [F. J. K.]

7.—Wolbarst states that a number of cases of gonorrhea in boys have come under his notice within the past two years. Twenty-two cases have been observed in patients ranging in ages from 18 months to 12 years. The diagnosis of all these cases was confirmed by a bacteriological examination. [F. J. K.]

8.—Scott writes on "the prevention of tuberculosis in babes born of tuberculous parents." He reports one case of chronic tuberculosis which occurred in a young married woman, 19 years of age. She was delivered of a baby girl weighing five pounds. The child was fed on modified cow's milk, and all communication between the mother and the child was prevented. At the time the author presented this report, the child, now three years old, appeared to be in perfect health. He reports a second case of acute tuberculosis which occurred in a young woman, married at twenty years of age. She enjoyed good health during pregnancy and during her confinement. On the twenty-seventh day after her confinement, she presented signs of acute pulmonary tuberculosis. The child up to this time had been nursed by the mother. Death occurred 16 weeks after confinement. The infant also developed tuberculosis and died a week after the mother's death. [F. J. K.]

9.—Norbury discussed "the etiology of parietic dementia" and deduces the following conclusions: (1) Syphilis is the factor in chief which causes parietic dementia. (2) Infectious fevers with their toxic influences are contributing etiological factors. (3) Heredity is a potent factor.

ROBERT REYBURN.

1.—Mann remarks that the operations of cello-hysterectomy and cello-hysterotomy are not properly rivals. Each has its proper place. In the elective Cesarean operation with the woman in good health and all the conditions favorable in the hands of skilful operators the mortality has been reduced below 5 per cent. In all cases in which the cause of the obstruction can be removed without injuring the uterus or both ovaries, or when the patient is suffering from a curable disease as eclampsia, the uterus must be left, except in the presence of sepsis or uncontrollable hemorrhage. The other advantages of the Singer operation are, that for the ordinary surgeon it is easier of performance; it enables the woman to become pregnant again; it does not interfere with menstruation or in destroying the sexuality of the woman; nor is it followed by the nervous symptoms of the menopause. Mann protests against the choice of hysterectomy simply for the purpose of preventing future pregnancy. The conditions

indicating hysterectomy are the presence of infection within the uterus, and any serious injury to the uterus by attempts at delivery. Disease of both ovaries necessitating their complete removal, would do away with the advantages of leaving the uterus. Cancer of the cervix is also an indication for the Porro operation. When the patient is greatly reduced, this operation is also indicated. Rupture of the uterus, if the abdomen be opened, should be followed by complete removal. Mann gives the technique of both operations as performed by him. [W. A. N. D.]

2.—In speaking of the pelvic indications for the performance of Cesarean section, Williams first considers the frequency with which contracted pelvis occurs and the methods of treatment which have been employed. He found 278 contracted pelves in 2123 consecutive cases of labor; that is, a frequency of 13.1%. He remarks that many of these cases occur in colored women. The race of the patient is not only of importance in determining the absolute frequency of contracted pelves, but his observations have shown that the variety of deformity varies markedly in the two races. The simple flat pelvis is the variety most frequently met in white women, after which the generally contracted, irregularly contracted and rachitic pelves follow in the order given; while in black women the generally contracted pelvis is the most frequent variety, after which comes the rachitic, then the flat and lastly the irregularly contracted form. 199 of the 278 women had spontaneous labors (71.58 per cent.), which is about the usual average. The colored women have comparatively easy labors. As regards treatment, labor was not induced in a single case. He believes that this operation when performed sufficiently early to give satisfactory results from an obstetric standpoint, is attended by an ultimate fetal mortality of nearly 50 per cent. The women are allowed to go to term and enter the second stage of labor. If, then, at the end of an hour, the head does not become engaged, such operative procedures are undertaken as may appear indicated. The corrected maternal mortality was 0.72 per cent. 36 children were born dead or died shortly after delivery, a gross mortality of 12.96 per cent. 18 of these children, however, died from causes not connected with the pelvic contraction. Of the remaining 18 seven children were dead when the case came into his hands, leaving 11 children, or four per cent., who died as the result of his treatment.

[W. A. N. D.]

3.—In considering the place of symphysiotomy as contrasted with Cesarean section, Jewett concludes as follows: Symphysiotomy is still a useful operation within a limited range in pelvic contraction. It is suited to conditions in which only very little additional space is required for delivery. It is a valuable resource, therefore, in cases in which forceps unexpectedly proves inadequate. Axis-traction forceps with the aid of posture should always be tried before resorting to symphysiotomy. Its results would be much improved by restricting it to pelves with the conjugate of not less than 7.5 cm. (3 inches) in simple flattening or 9 cm. in general contraction. Under equally favorable conditions its total mortality should be no greater than that of Cesarean section. When the pelvic space permits it should replace the Cesarean operation in the presence of exhaustion. It may be elected primarily as an alternative of Cesarean section when the operator can be assured that the degree of obstruction is well within its safe limit. Within its proper field symphysiotomy is better than the Cesarean section for an operator of little experience in abdominal surgery. [W. A. N. D.]

4.—Reynolds, in speaking of the elective Cesarean section, states that his experiences have led to the following conclusions: (1) The Cesarean section performed late in labor, or in the presence of infection of the uterus, or other complicating constitutional conditions, has been shown by the experience of almost every operator who has tried it, to have so high a mortality as to be totally unjustifiable when performed in the interest of the child alone. (2) When a Cesarean section is performed on a healthy woman early in labor, and under otherwise favorable conditions, for merely mechanical indications, it has in skilled hands no mortality other than the fractional percentage incidental to all considerations *per se*. (3) The inconveniences and high morbidity-rate of symphysiotomy render it distinctly inferior to the section as an operation of

choice, but it is an operation which as compared to craniotomy or prolonged and forcible high-forceps work without it, involves almost no increased risk of life. It is, therefore, the operation of choice in the limited number of neglected cases in which the pelvic contraction is within the range where the extraction of a living child without symphysiotomy is difficult or impossible, but after symphysiotomy is safe and easy. (4) The induction of premature labor for contracted pelvis results in so high a fetal mortality as to be unwarranted when placed in opposition with the performance of the Cesarean section at the beginning of labor and in favorable cases. [W. A. N. D.]

5.—Booramman Reed discusses the hygienic and mechanical treatment of heart disease. In two ways the heart may be injured by the toxic products of imperfect ingestion, as well as by suboxidation and other faults of metabolism: (1) Its muscle may be impaired by the circulating poisons, and at the same time be poorly nourished in common with all the other muscles, by the blood previously impoverished from the same cause; and (2) its work may be increased by the contraction of the arterioles resulting from the action of the alloxuric bodies and other products of imperfect metabolism. Reed emphasizes the value of preventing the threatened cardiac hypertrophy and the renal changes by the selection of a proper diet, not too nitrogenous, and an amount of careful, moderate exercise in the open air and the oxidation of food. He believes that (1) Cardiac disease is often due to auto-intoxication, especially to poisoning by the alloxuric bases; (2) cure, or amelioration in such cases requires at first, in addition to an appropriate diet, not too nitrogenous, the utmost practicable rest of the crippled organ. This cardiac rest may be further promoted by very gentle exercises which dilate the capillaries without taxing the heart; (3) the Nauheim method of treatment spares the heart by dilating the too contracted arterioles in two ways—(a) by stimulating the peripheral circulation through carbonated saline baths; and (b) by massage and forms of exercise (Widerstandsgymnastik) so mild as not to quicken the pulse.

[T. L. C.]

Superalimentation in Pulmonary Tuberculosis.—Candido of Paraná, has written an interesting article upon the evils of superalimentation in phthisis, in *Brazil-Medico*, (June 1, 1901, No. 21), which he read before the National Academy of Medicine of Brazil. In it he reiterates the inconveniences of superalimentation, though Debove, Broca, and other prominent men counsel it. Alimentation may be sufficient when the food ingested just balances the output of energy, and the individual remains in good health; insufficient when emaciation follows; and excessive when more is ingested than is needed to make up for the energy spent. Candido considers superalimentation impracticable, inefficacious, and harmful. It is impracticable because more or less anorexia already exists; inefficacious because the pulmonary lesions do not improve, though the patient does gain in weight; and harmful because it causes dyspepsia, with even more marked loss of appetite. Letulle and Rendu have both shown this. Candido therefore, agreeing with Pujade, discounts excessive feeding in pulmonary tuberculosis. Enough food should be given, but not superalimentation. [M. O.]

Tuberculous Pericarditis with Large Effusion.—At a recent meeting of the Medical Society of the Paris Hospitals, (*Bulletin et Memoires de la Societe des Hopitaux de Paris*, 1901, No. 11), Dr. H. Rendu reported a case of tuberculous pericarditis in a man of 34. On admission to the hospital he was very dyspneic, his pulse was small, rapid, and irregular, a typical *pulsus paradoxus*. The precordia bulged, there were edema of the anterior chest wall, precordial dullness, and tympany over the left lung posteriorly. Rendu punctured the pericardium, withdrawing 800 g. of sero-fibrinous, slightly hemorrhagic fluid. Four weeks later the effusion again caused the same symptoms. 1250 c.c. were withdrawn, and 1 g. of camphorated naphthol was injected. Six weeks later he was well. And he has kept very well since, considering his pulmonary condition. The size of the effusion, and the great quantity of mononuclear leukocytes in it showed that the condition was probably tuberculous. The sphygmograms give plainly the changes in the pulse. The result is exceptional. [M. O.]

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fiftieth Annual Meeting Held at Philadelphia, September 24-25, 26th, 1901.

(Continued).

SECOND DAY—MORNING SESSION.

The meeting was called to order at 9.30 A. M., and the minutes of the previous meeting adopted as read. Dr. F. H. Wiggan, of New York City, Secretary of the New York State Medical Association, and Dr. E. Eliot Harris, of New York City, Chairman of the Committee on Legislation of the New York Medical Association, were then introduced as visiting delegates. Both delivered short addresses to the Society, and gave a brief account of various methods employed by the New York Society. The scientific schedule of the day was then begun.

Address in Medicine by Dr. John B. Donaldson, of Canonsburg, Pa. The speaker expressed his belief that with further progress, typhoid fever and tuberculosis would become as preventable as smallpox. He referred to the achievements in medicine during the last century, notably the discovery of the bacillus of diphtheria and the introduction of antitoxin. The progress of surgery during the last century which may be well termed the surgical era, was referred to, with especial reference to anesthesia and the work of Lister. He highly recommended the preventive measures against disease that had been adopted, and especially the treatment and modern crusade against tuberculosis. Cholera and yellow fever have been halted at our shores and the anti-expectoration laws are continuing to guard the populace against the transmission of infectious diseases. The valuable lives that are saved by the employment of the microscope and tuberculin test, and open air life, cannot be computed in dollars and cents. But we need not send the patients away for open air treatment in cases of tuberculosis, for our own mountain and hill tops are splendidly adapted for this purpose. The existence of slums in cities is to be deplored, especially as there is no excuse for their existence. The application of money for the eradication of this sanitary evil is in many instances far more desirable than the erection of libraries. As an illustration of this he quotes the present sanitary condition of the city of Havana, where yellow fever has been stamped out by diligent and scientific men. Why should not such matters be as strenuously observed for instance in the city of Pittsburg as in Havana. The water supply in many localities is becoming a serious question, filtration only straining the coarser particles. The raising of the standard of medical education fortunately leaves no room for fakirs and impostors. Dr. Donaldson predicts a speedy dissolution of all such detrimental institutions and their speedy replacement by those teaching sensible medicine. In conclusion he calls attention to the necessity of the careful scrutiny of the bodily excretions.

Gastroptosis and Its Treatment by Dr. J. Dutton Steele, of Philadelphia. A table of fifty consecutive cases of gastroptosis was shown in all of the patients, the diagnosis having been made by gastric inflation. After quoting the varieties of gastroptosis, the etiology was referred to. The most frequent causative factor is corset lacing, causing pressure from above upon the stomach. In men the wearing of stiff belts may give rise to this affection. Occupation may also play a role, especially in the case of engine drivers who sustain a shaking of a full stomach. It is important to differentiate between simple dilatation of the stomach and gastroptosis. The inflation test is the most valuable method of obtaining the size and position of the viscus, the fallacies of other methods than inflation being shown. Inflation may be produced by the intragastric liberation of carbon dioxide following the administration of sodium bicarbonate and tartaric acid. The test must be performed quickly with the patient in the recumbent position and diagnosis assisted by auscultatory percussion. Other methods have also been employed, such as the introduction into the stomach of a

distensible balloon at the end of a tube. The simpler method employed the better the results. The physical signs elicited by the bulb method are high pitched tympany on percussion, a distension visible against the anterior abdominal wall, and when the bulb is compressed, a metallic ring is heard, which, however, loses its metallic character when it is present beyond the confines of the viscus. In these cases the examination of the gastric contents is absolutely of no value, some cases showing normal conditions, some subacidity and others hyperacidity. The treatment consists of abdominal binders, preferably rectangular pads six by four inches, and otherwise similar to those used in floating kidneys. The speaker showed a diagram, illustrating the various displacements of the different parts of the stomach. Permanent restoration of the position of the stomach without operation may result favorably, but it is rare.

Movable Kidneys; Their Effects Upon the Gastric and Intestinal Functions, by Dr. Boardman Reed, of Philadelphia. The author believes that downward displacement of abdominal viscera ought to be considered together, as they are usually associated. It is very frequent in women, and he quotes Stockton, who estimates that 50% were affected by enteroptosis. He believes that many women are treated by pessaries, tampons, and even operation, when the trouble is really above. The various degrees of nephroptosis were described. Corsets, heavy skirts, etc., had much to do with the etiology, and the old theory that pregnancy was responsible for this affection is being disproved. Disturbances of digestion occur, there being pain one to three hours after eating. He calls attention to the stimulation of the gastric glands which frequently occurs in these conditions, as well as the vomiting of liquid so acid as to put the teeth on edge, fermentation, however, being absent. If the kidney process progresses, there will be insomnia, mental depression and even neurasthenia. Dilatation of the stomach may ensue. The diagnosis is to be made by palpation alone, the symptoms themselves not being sufficiently diagnostic. The peculiar shape of the kidney must be recognized and the organ made to slip through the fingers. Regarding prognosis Dr. Reed believed that a cure may now be obtained in a certain number of cases if the patients are in a position to carry out the instructions and subject themselves to medical supervision for a long time. The treatment consists in confinement to bed, a certain modification of the rest cure and the application of suitable pads with an elastic belt. The neurasthenia can be overcome by massage, electricity and good food, and also tends to replace the natural cushion of fat, the absence of which often causes nephroptosis. In extreme cases the pad and belt may also have to be kept on during the night. Drugs are little needed, tonics may be employed temporarily to fortify the constitution and the stubborn hyperchlorhydria may have to be combated, requiring intragastric faradism. The chief aim is to strengthen the patient and his or her abdominal muscles.

Dr. R. H. Gibbons, of Scranton, Pa., in discussing the subject, believed that it was a mistake to assume that the application of a pad keeps the kidney in place. He quoted Edebohl, who claimed that appendicitis is often caused by a loose right kidney interfering with the circulation and causing congestion. He concurred with this authority regarding the surgical treatment and removing the appendix through the same incision. Dr. C. P. Noble, of Philadelphia, considers the rest cure and the fattening theory of value in cases where there is a moderate amount of displacement. Where the symptoms are absent, patients may be left alone. In suitable cases operation is decidedly indicated. The discussion was continued by Dr. J. A. Downes, of Philadelphia, and closed by Dr. Reed, who emphasized that movable kidney should not be considered *per se*, and, as many surgeons will concur with him, is not always cured by surgical intervention.

Dieter's Crises in Movable Kidney, by Dr. John G. Clark, of Philadelphia. The author substituted the title, "enteroptosis in general." Dieter's crises, as is well known, are due to a tortuosity of the ureter caused by a backing up of the urine and the ensuing pain, which is somewhat similar to that observed in a case of calculi. The etiology depends upon lack of exercise of the abdominal muscles and a separation of the recti. He stated that in women who had rapidly born children, the muscles were well separated and the pulsation of the aorta could be easily felt;

this latter phenomenon has itself frequently formed a subjective symptom, and has led the patients to believe that it was of such importance as to require them to consult medical aid. The operative treatment consists in carrying the incision well up above the umbilicus excising the relaxed tissue and bringing the recti well together. Medical treatment will to a certain extent give relief, but surgical treatment is requisite in obstinate cases. Dr. Clark showed models illustrating the pathological anatomy of the condition, and the objects which aim to restore the continuity and the tonicity of the structures. Surgical intervention should be followed by rest, support and carefully conducted massage. The paper was discussed by Dr. R. H. Gibbons.

Report of Several Cases of Infective or Malignant Endocarditis, by Dr. A. O. J. Kelly, of Philadelphia. Dr. Kelly believed that an acute endocarditis is a single process, with gradations depending upon the virulence of bacteria and the resistance of the individual. There are cases beginning benign and which subsequently become malignant. Bacteria have been found not only in the cardiac valves, but also in secondary involvements, such as emboli. The condition is really a pyemia or bacteremia, and should be so considered. It is not always necessary for the bacteria to lodge on the valves; the toxins should also be taken into consideration. The diagnosis depends upon the leukocytosis, which should be looked for not only from a numerical standpoint, but also from a differential one; second, a bacteriological examination of the blood, the importance of which is demonstrated by the fact that the author has on several occasions been able to demonstrate the organisms during life and subsequently upon post-mortem examination. Third, the symptoms referable to the heart, as well as the so-called arrhythmic disturbances.

A Few Notes on the Salts of Sulpho-Carbolic Acid, by Dr. Edgar Moore Green, of Easton, Pa. This paper constituted a plea for the more frequent employment of the salts of sulpho-carbolic acid and a statement of the author's results. He believes that it is a convenient method of administering carbolic acid and describes the physiological action of these combinations. He has obtained good results with combinations, of acetanilid and the sulpho-carbols of sodium and of zinc.

Primary Abdominal Tuberculosis, by Dr. Flick, of Philadelphia. The speaker stated that by the title of his paper there was meant the primary lodgment of a colony of tubercle bacilli in some intra-abdominal tissue. Surgery and pathology have discredited the long accepted theory that primary tubercular infection always has its seat in the lung. The statistics of Williams, of Johns Hopkins Hospital, based upon observations, after a number of celiotomies, and those of Israel, of Berlin, who believes that one-third of the diseases of the kidneys where there is pus in the urine were due to primary tubercular infection of those organs, all seem to support the theory of primary abdominal infection. Regarding the manner in which the tubercle bacilli gained access to the abdominal cavity he stated, that by reason of the fact that the tubercle bacillus required a certain temperature for its propagation, it can hardly be believed how a colony can thrive on an abraded surface of the intestines, especially when we consider the intestinal movements and their appended secretions. The diagnosis of primary abdominal tuberculosis is difficult, and we must look to the surgeons for diagnostic factors. The tuberculin test in these cases is too meagre to warrant conclusions. The treatment is as yet unsettled and up to now is still restricted to the surgical domain. It is of interest to note that the opening of the abdomen itself without the removal of tissue has been beneficial, but it is only speculative how this does good. The introduction of iodoform into the abdominal cavity during operation is highly recommended. The discussion on this paper was opened by Dr. Joseph Price of Philadelphia who considered Dr. Flick's paper from a surgical point of view. The surgeon is in a position to observe the infection from a macroscopical standpoint. The treatment has really been stumbled upon as many abdominal sections were really not made with a premeditated diagnosis, and especially in the cystic forms did the cures result from mere accident. For a number of years Dr. Price has not hesitated to open the abdomen for abdominal tuberculosis. Most of the operations have been done late, the surgeons frequently being afraid of adhesions, and Dr. Price furthermore stated that a

surgeon who fears adhesions ought not to open an abdomen. He considers the introduction of Iodoform of value. Later on when the abdomen had again to be opened these eight inches were found perfectly healthy. The drug is not as toxic as has been supposed. Abdominal tuberculosis is a condition that justifies thorough and complete intraperitoneal intervention. He knows of no condition where one can take the liberty of manipulation as in abdominal tuberculosis. Dr. Price's maxims are, operate early, free the viscera, liberally dust with Iodoform, and drain. The discussion was resumed by Dr. Mordecai Price, of Philadelphia, who is thoroughly convinced that infection in these cases occurs through the blood and lymphatics from food that is infected with tubercle bacilli. If the symptoms are present he considers it his duty to open the abdomen. He advises early operation. Dr. James Tyson, of Philadelphia, believes the diagnosis difficult and the tuberculin test a thorough one, especially in tuberculosis of the peritoneum. Dr. S. Solis Cohen stated there was not one agent in the materia medica which could combat tuberculosis as well as Iodoform. The drug can be administered internally without much gastric derangement. Notwithstanding the theories of Koch and Theobald Smith, he stated that we nevertheless were in possession of sufficient evidence to put us on our guard as to the reciprocal transmissibility of human and bovine tuberculosis. Dr. Flick, in closing the discussion, called attention to the fact that it must not be forgotten, the mode of entrance may be the alimentary canal, and from other sources than food. Respiration may carry the germs to the bronchi, thence to the lymphatic glands, then to the thoracic duct and finally to the heart and circulation, a comparatively short route from the lungs to the abdomen. He also believes that Iodoform is a most valuable drug in these conditions.

AFTERNOON SESSION.

The first paper in the afternoon session was the address in hygiene by Dr. E. B. Borland, of Pittsburg, Pa., who alluded to the discoveries of the last century which probably have paved the way for preventive medicine. Typhoid fever and tuberculosis seem to demonstrate the want of the potential factors, pure air, pure food, pure water and sunshine. He spoke of the individual communion cup in churches and apparent defects in military hygiene as exemplified by the many deaths during the Spanish War of previously healthy and robust soldiers. He believes that the epidemic of smallpox now prevalent is due to the negligence of the authorities in not providing special hospitals, as well as to the ignorant anti-vaccinationists. Special hospitals should be provided for smallpox, scarlet fever and diphtheria in all places of over one thousand inhabitants, and in localities of over twenty thousand inhabitants each hospital should have three wings, each of which to be devoted to one of these diseases. Such institutions should be placed in the centre of a plot of land comprising one acre in order to dispel the fear of the public. He advocates cooking schools, as improperly cooked food has much to do with disease. The author stated that if the Women's Christian Temperance Union would devote more time to cooking instructions, probably more would be done against intemperance. Young girls ought to be taught cooking just as well as boys are taught bookkeeping. The sexes should be separately instructed in physiology by a plan of lectures which would elucidate such matters that would prevent them from becoming victims in the future of quackery and enable them to realize it. Much inebriety is due to the spirits contained in proprietary medicines, and causes much moral degradation. In the interest of public decency, if for no other reason, this should be stopped. The next subject taken up by the author was that of barber shops. Missouri requires the rule of the Board of Health relative to barber shops to be posted in conspicuous places in each shop. It furthermore requires that a clean towel be used for each customer, that the paraphernalia be sterilized in a suitable oven, and that the barber must wash his hands after he has attended each patron. Another subject of hygienic importance is the humidity of houses in winter. Experiments have shown that at a time when the humidity within the house was 30% it was 71% outside. This is too much of a strain upon the respiratory passages, and can be obviated by the installa-

tion of an air moistening apparatus. This has been done with excellent results in a certain telephone building, and considerably reduced the number of bronchial affections among the numerous operators. Contaminated water may not only be held responsible for 50% of cases of enteric fever, but causes much suffering in many tubercular subjects. Regarding house plumbing, the speaker stated that disaonest contractors and plumbers in the absence of suitable restraining laws, frequently take advantage of householders. Legislation on this subject should be so modified that contractors can be held legally responsible. In taking up the subject of hygiene as related to tuberculosis, the author quoted Koch, that sputum is the chief conveyer of the infection. The author laid considerable stress on the anti-spitting crusade and gave a geographical description of the localities where it is enforced, New York leading in the anti-expectorating crusade. Dr. Borland called attention to the necessity of protecting our shores, by keeping out cases with ulcerative tuberculous lesions. It is to be presumed that the house fly conveys tuberculosis just as it did typhoid fever in the military camps. It will require a long continued observation to determine the feasibility of Koch's theory regarding the reciprocal transmissibility of human and bovine tuberculosis. The public should be instructed to go hand in hand with the municipal authorities in its crusade against this disease. The author referred in the most emphatic way to the doubtless conveyance of tuberculosis into the home by the long skirts of women which sweep up the infection from the streets, and exhorts the women to give this matter due consideration.

The Histories of Three Accidents in Tapping the Chest, by Dr. J. C. Lange, of Pittsburg, Pa. The first case resulted in instant death after the introduction of the aspirating needle into the seventh intercostal space posteriorly on the left side. The patient had had an aortic murmur, a dilated heart, arteriosclerosis, and albumen and casts in the urine. His anasarca had resulted in a large bilateral hydrothorax, and it was for the pulmonary edema that aspiration was performed in order to increase the patient's respiratory power. The patient was not excited or afraid of the tapping, but the instant that the needle penetrated him, he died of heart paralysis. Post-mortem examination showed a diastolic overfulness of dark blood, no ante-mortem clots and a hydropericardium. The second case reported was that of a male aged 23 with a history of croupous pneumonia three years previous. His respiratory capacity was not fully restored, and he continued to expectorate. He had a pleural distension on the right side, and aspiration gave vent to a substance which was so mucilaginous that it passed with difficulty through a large aspirating needle. The discharge was sterile. The cough which usually follows aspiration and is due to pleural irritation, caused the author to stop in his interference from five to ten minutes. Examination showed that areas which were previously flat were now resonant. Aspiration was continued and now the patient, with a terrified cry, became purple in the face and would have run away had he not been restrained. Blood gushed from the trachea. Morphine was given, and hemoptysis gradually decreased for four days. The patient, in whom no other chest lesion was present, was sent to the mountains, and improved, but returned again with a pleural effusion, fifty ounces of effusion being removed this time without accident. A second time he returned with another pleural effusion, which now contained pus cells. Aspiration was this time performed by means of an incision into the seventh intercostal space and one inch in length, which subsequently was increased to two inches, resulting in a gradual aspiration into the dressings, which were applied over the wound. Two and a half years thereafter no symptoms were present, except a diminution in fullness in the sub-clavicular region. The third case was that of a woman 58 years of age with biliary cirrhosis and an acute pleurisy on the left side. Four weeks after convalescence three pints were aspirated, and hemoptysis occurred, which gradually decreased, the patient dying sixteen months thereafter.

TWENTY-NINTH ANNUAL SESSION OF THE AMERICAN HEALTH ASSOCIATION.

(Continued from Page 521.)

RESOLVED, that this Association is of the opinion that sufficient facts have not been offered by Professor Koch or other investigators to prove that human and bovine tuberculosis are different diseases. It is further of the opinion that the variability under different environment common to micro-organisms may, on further investigation, be found sufficient to account for the differences that have been noted and that the germs of these diseases may not be proved to be closely allied or identical. Irrespective of the question of the communicability of bovine tuberculosis to man, the inspection of animals and premises is absolutely necessary, in order that:

1. The meat and milk of animals suffering from this and other constitutional diseases be not used as human food.
2. The sanitary condition of dairies, stables, etc., as regards cleanliness, water-supply and ventilation may be maintained.
3. That the health of dairymen and other handlers be closely supervised to prevent the spread of diphtheria, scarlet fever, human tuberculosis, etc., through the milk supply.

RESOLVED, that this Association while desiring to express its positive opinion as to the importance of dealing with animals and their products as indicated in the preceding resolutions, does, at the same time, insist upon the necessity of dealing with the still greater dangers, now universally recognized, of the transmission of tuberculosis from one person to another by continued personal association through inhalation of infected living rooms, the contamination of clothing, handkerchiefs and similar objects with sputum and other secretions, and would therefore urgently recommend that municipalities adopt regulations, as follows:

1. Against expectoration on pavements and in other public places.
2. For the compulsory notification by physicians of cases of tuberculosis, in order that literature may be supplied to householders and municipal aid given, where necessary, to lessen the dangers to the families of infected persons.
3. For the establishment of municipal sanatoria for the benefit of persons and families of limited means.
4. For the regular inspection of tenements, factories, workshops, schools and other public institutions, to promote cleanliness, ventilation and other sanitary conditions.

"The Prevention of Yellow Fever," by Dr. Walter Reed, Surgeon, U. S. Army.

Dr. Reed's excellent paper on this important subject was illustrated with drawings and a diagram of the female yellow fever mosquito (*Stegomyia fasciata*). There have been not less than 500,000 cases of yellow fever in the United States during the period from 1793-1900. The commercial loss sustained through the epidemic of yellow fever at New Orleans, in addition to 41,348 deaths, amounted to \$10,752,500.00.

The Doctor claimed that the mosquito *Stegomyia fasciata* serves as the intermediate host for the parasite of yellow fever. It has been demonstrated that an attack of yellow fever cannot be induced by the most intimate and prolonged contact with the clothing and bedding of yellow fever patients, even though these articles had been previously thoroughly soiled with the excreta of such patients. This mosquito has been found in all of the principal cities of Cuba. It has also been found in other cities in the West Indies, Europe and in the South and South-western part of the United States. This mosquito has a large distribution in the warmer countries of the globe and especially at low altitudes.

As to the breeding places, this mosquito has been found in rain water barrels, in sagging gutters containing rain water, in tin cans that have been used for removing the excreta and which still contained a small amount of fecal

matter, in cesspools, also in tin cans placed about table legs to prevent the inroad of red ants. This mosquito will breed in any collection of still water, rain or hydrant, and the presence of fecal matter does not seem objectionable. The female lays her eggs on the surface of the water in pairs, and it takes 12 days for the young to develop. The mosquito will bite at a temperature of 60° and above. There have been cases of yellow fever reported bitten by insects at intervals varying from 12 to 57 days after contamination. Here the dangerous interval was 45 days.

The problem of preventing the spread of the disease, when imported, seems to resolve itself into the simple question of excluding mosquitos from access to the sick individual, and of destroying those insects that have already become infected. We can leave out of consideration any danger from wearing apparel or baggage, which may be dismissed as harmless. The fear that has been entertained that infected insects may be imported in boxes or trunks is believed to be absolutely groundless by the author, for the reasons that mosquitos require water for their existence and in its absence they die within five or six days. As a fumigant pyrethrum powder is preferred, although sulphur and formaldehyde are used. The pyrethrum is burned in proportion of one pound to 1000 cubic feet of air space. At the expiration of 3 hours the room is opened and the mosquitos swept out and burned.

The conception of yellow fever as a "filth" disease must be abandoned and our attention turned to yellow fever as a mosquito-borne disease. If in the city of Havana a comparison is made of the mortality of the epidemic year of 1900 with the present year of 1901, during which sanitation based on the demonstration that yellow fever is propagated by the mosquito has been enforced, there will be observed a great reduction in favor of the latter, namely, 411%. The sanitary regulations put in force February 15, 1901, by Dr. Gorgas resulted in freeing Havana from yellow fever within three months. The Doctor further said: "We believe that no quarantine restrictions should be placed upon either passengers or cargo from non-infected ports. In the case of a vessel loading in midstream at an infected port by means of lighters, we believe that she can only receive infection in one way, i. e., by passengers who have been exposed to yellow fever on shore and who, coming on board, may thereafter be seized with the disease. The possibility of infected mosquitos reaching the vessel, either by flight or by means of lighters, may be dismissed." It is not considered necessary to disinfect the cargoes of ships, unless there is ground to believe that the vessel might possibly have carried the yellow fever mosquito in transit, which is unlikely. The chief duty of quarantine officers in future will lie in the detection of mild or very mild cases of yellow fever."

The contribution of Dr. LEEGO, President of the Supreme Board of Health of Mexico was: "10th Report on Yellow Fever Cases Observed on the Two Coasts of the Mexican Republic from the 17th of September, 1900, to the 31st of August, 1901." The Doctor said that the sanitary authorities of Mexico have imposed on themselves the obligation of never attempting to hide the diseases that prevail in its ports in frontier towns. Within the above named period cases of yellow fever were observed in Vera Cruz. But it is expected that through the new sanitary works already begun in that city, together with an abundant supply of pure drinking water and a system of sewage, the same good results will accrue as obtained in the city of Havana. The port of Tampico is likewise receiving sanitary attention. Recommendations have also been made that in these places, where yellow fever reigns in an endemic or sporadic manner, the residents protect themselves against the bites of the mosquito (*Culex fasciatus*), as well as to prevent those, that have bitten yellow fever patients, from escaping out of the wards in which those patients are attended and infect the immunes outside of the hospital.

A LECTURE ON STRANGULATED HERNIA.*

By CARL PFISTER, M. D.,
of New York.

Professor of Surgery in the New York School of Clinical Medicine.

Ordinarily, the student and junior practitioner are taught that when strangulated hernia is suspected, the first and only step, the imperative one, indeed, is to call in a surgeon. Thus most valuable time, especially in country practice, is lost by the delay. It is my purpose to show the error of such proceedings, first, on behalf of humanity, and second, for the sake of science. I insist that the general practitioner is fully qualified to treat a great number of strangulated hernias—even that he is able, in an emergency, to operate for relief of the strangulation.

For the clear understanding of our work, let us primarily consider what strangulated hernia is. The pathological feature of such a hernia is the incarceration or torsion of the intestine, obstructing the movement of its fluid or solid contents and obstructing the blood circulation in the intestinal wall. This leads to gangrene of the prolapsed gut below the point of incarceration. Strangulation is produced by the disproportion between the prolapse and the opening. Strangulations are clinically divided into:

1. Chronic strangulations, due to gradual accumulation of fecal matter in the prolapsed intestine;
2. Acute strangulations, with but slight, intermittent symptoms of increasing severity; and
3. Strangulations in which the onset is acute and shows manifestations which rapidly grow intense.

Little is known of the original mechanical cause of strangulation. Several established factors enter into its evolution: The hernial opening, its sac may become inflamed, or perhaps only engorged, there may be a sudden increase of the prolapse or of its contents, and finally, torsion, or knuckling of the gut, may occur. This last-mentioned condition does not seem to have received the attention it merits. Before entering into the details of diagnosis and treatment of the various acute forms of strangulation, let us discuss that kind of gradual incarceration which most frequently occurs in old people with large irreducible scrotal hernias of long standing.

This condition consists in obstruction to the passage of feces through the incarcerated intestine. The anatomical construction of the colon and the sigmoid flexure make them the most frequent sole contents of the hernial sac in such incarceration. The exciting cause of the incarceration may be food which is difficult of digestion, such as soggy bread, large quantities of potatoes and insufficiently chewed food. Slow peristalsis for a long time in an intestine within a hernial sac aids materially in arrest of its contents, readily predisposing it to obstruction. The rupture is gradually filled by the remains of undigested food. If discovered early, it may be possible to empty the contents of the hernial sac; but the hernia is rarely heeded until it gives either decided discomfort or marked pain. The

development of the condition which leads to strangulation is usually so gradual that professional aid is not sought until emergency has arrived. Then the descendent part of the gut has become widely distended and its ascending part entirely compressed.

The symptoms produced by this kind of incarceration are usually not of such a severe and alarming character as those of acute strangulation. But after some time antiperistaltic motions set in together with stercoraceous vomiting. This may last a comparatively long time without producing that collapse which presages, in the acute form of strangulation, a fatal termination. In beginning the treatment of these cases a light cathartic, such as castor oil, or a small dose of calomel, may be given. A high injection of cold water and the application of an ice-bag will stimulate peristaltic movements and diminish the size of the rupture. Frequently the application of heat produces more relaxation of the involved tissues than cold. It is, however, wise not to spend too much time on these preliminaries, but to resort promptly to taxis for the reduction of the strangulation. For this purpose the patient is placed on a table, preferably to a bed, because of the greater firmness of the former, and because it is more convenient for the physician's work. A pillow is placed under the patient's head and the foot end of the table raised, so that the patient lies with the pelvis elevated, which aids materially in overcoming and releasing the strangulation. We first attempt to reduce those loops of intestine which entered the sac last. Then we strive to gently express the contents of the gut which has grown adherent to the hernial sac. This attained, we endeavor to return the emptied gut to the abnormal cavity. It is always best to grasp the rupture with both hands that the force applied be equally distributed over the entire tumor.

Taxis is the principal treatment we depend upon in these cases. The prognosis of herniotomy is a very grave one in this condition, because we have to operate under most unfavorable circumstances in view of the very old age, poor heart action, and low vitality of the patient. These same circumstances mostly attend cases of coprostasis. General anesthesia is contra-indicated on having to deal with a purely mechanical obstruction, and not with a spasmodic, muscular, or other tissue contraction; therefore, narcosis would be of only very limited value. Special attention is given to this kind of strangulation, because it is just the form which occurs frequently in general practice and especially in country practice. There seems no room for disagreement that the whole management of such an occurrence contains nothing that the skilful practitioner could not do without specially trained assistance. The diagnosis is almost always clear and simple, and the treatment requires not much more than a little common sense.

Now, to consider the various forms of acute strangulations, beginning with those in which the first symptoms seen are not severe, but which become so after several periods of intermission. The pathological and anatomical changes which take place in a strangulated hernia are beyond the scope of the present discussion. The first noticeable and most

*Delivered before the New York School of Clinical Medicine.

important symptoms of a strangulation are irreducibility and immobility of a hernia, irrespective of whether a truss has been worn or not. Up to then the hernia was easily reduced by the patient. Stercoral retention is another important diagnostic factor, as is vomiting, in the more acute stages. Where these symptoms are combined in a person afflicted with hernia, the diagnosis can be almost infallibly made. This condition is the chief reason which urges the patient to summon professional aid, after many ineffective efforts for hours and even for days to reduce his rupture. The diagnosis of the patient's desperate state is thus often made, and correctly so, before the practitioner's arrival. Several personal experiences of somewhat more than ordinary diagnostic and clinical interest will illustrate the type of slow incarceration of hernia.

CASE I.—35 years old, reported a right femoral hernia of one year's duration. It had been reducible, and was always controlled by a truss without causing him the slightest trouble; now for a day his rupture could not be reduced. Examination revealed a swelling of half the size of a hen's egg in the right groin. The swelling was hard and immovable, somewhat tender to the touch, and yielding no impulse from coughing. The bowels had moved eight hours before. No other symptoms. Normal pulse. Adenitis was diagnosed, wherein one of my most prominent surgical colleagues agreed. I prescribed ichthyol ointment and sent the man home. The next day he returned, but his condition was not changed at all, and he felt comparatively well. The following morning I was summoned to the patient's house and found him with all the symptoms of strangulation. He vomited, his bowels had not moved, the skin was moist, his forehead covered with cold perspiration. The swelling itself showed no change excepting increased tenderness. I immediately operated under local anesthesia. (4% solution of eucaine). Taxis was not attempted because of the severe pain, and I had no assistant for general anesthesia. I made a skin incision two and a half inches long across the highest point of the tumor, and, coming immediately down to the hernial sac, found that the neck of the sac was greatly constricted by a number of greatly enlarged infected glands, incarcerating its contents after removal of these glands the hernia was easily reduced. The skin-wound was closed by interrupted sutures. The patient stood the operation, lasting fifteen minutes, well, and made a rapid recovery. In this case you will see the strangulation was produced by a purely mechanical process, as occurs only occasionally, through the formation of a neoplasm; a very rare form of strangulation, in which the originating causes are neither in the opening nor in the sac. This operation was done, by the way, without assistance, in poor tenement house surroundings, and its success was due, essentially, to prompt operative intervention.

CASE II.—F. M., 21 years old, came with a very slight right inguinal hernia which he had first noticed about four weeks before. He had worn a very light truss for one week, and complained of pain which greatly increased with the pressure of the truss. The rupture did not enter the scrotum and was very soft and easily reducible. At his request, because of the intolerable pain, I transferred the patient to St. Mark's Hospital for operation. Having, after the skin incision, divided the fascia of the external oblique, a very small hernial sac was found, in which, when opened, I discovered, to my great surprise, the much-enlarged appendix, knuckled, and perfectly adherent to the wall of the sac; and within this appendix, upon dissection, I found three bird shot. Here was at once the explanation of the severe and unaccountable pain. The young man had played slingshot, frequently carrying shot in his mouth, and had swallowed some of them. The sac was ligated and dissected out, and the wound closed by Bassini's method. Two and one half weeks later the patient was discharged from the hospital in perfect health. Though a complete strangulation had not taken place in this instance, the inflammatory process in the sac would soon have led to it, and, with the appendix involved, we

should have had to do with a very severe case, as that troublesome organ will become necrotic in a very short time. In this case the dangerous outcome would have been inevitable, since torsion would have been arrested circulation.

CASE III.—G. N., 17 years of age was referred to me one week before Christmas, suffering from an irreducible umbilical hernia, which was probably congenital, but had never caused him trouble or pain until a couple of weeks before this time, when he had experienced frequent distress accompanied by vomiting. We agreed to defer the operation until after the holidays. On December 22d he returned, complaining of increased pain and vomiting; his bowels had moved. I sent him to the hospital immediately and operated on the following morning. The hernia consisted of adherent omentum, but through the very small opening a little segment of intestinal wall had slipped and become caught. This was easily pushed back, and the wound closed by three layers of sutures; peritoneum, fascia and skin. The patient left the hospital after two weeks.

Umbilical hernias in men so young are extremely rare, and especially so if of slender build, as was this patient. The treatment of the different forms of strangulation being in general the same, let us first consider the most important clinical and diagnostic characteristics of acute strangulation. The pathological changes which take place in the involved tissues are divided into three stages: first, the venous hyperemia; second, inflammation, and third, gangrene. In the first stage, blood stasis in the veins of the prolapsed gut is caused by pressure. The arteries not yet being obstructed, transudation through the serous edematous intestinal wall into the hernia sac occurs and forms the so-called hernia fluid. The second stage involves those tissues situated above the strangulation, whose arteries are still uncompressed, and are consequently hyperemic, in contrast to those parts below the strangulation, where the blood supply is entirely obstructed. The third stage is necrosis of the prolapsed gut consequent upon entire interruption of the blood supply. The most important macroscopic changes in the appearance of the involved intestine are from light to dark, brownish red and grayish discoloration, the formation of small, hemorrhagic spots, thickening of the wall, the formation of strangulated grooves and hernia fluid, adhesions, and the spreading of the inflammatory process to the external surroundings. While the clinical symptoms of strangulated hernias are usually very striking, it may chance that some of these symptoms are not present; so that, in view of the fact that a hernia may become strangulated at the moment of its first appearance, it is not always a simple matter to make a correct diagnosis. For instance, many strangulated hernias are very tender, the slightest touch causing exquisite pain; and yet, the absence of pain does not by any means exclude strangulation. Vomiting alone does not prove strangulation; the inflammation of an empty hernial sac, or of omentum will produce this result; the same is true of the retention of stools.

We can make a definite diagnosis only by consideration of all symptoms and careful examination of the inguinal and femoral regions and of the abdomen. The last named, being soft in the beginning, becomes tense and tympanitic when circumscribed peritonitis, primarily localized in the hernia sac, has spread over the peritoneum. Should the femoral or inguinal region present a tumor, hard and tense and increasing in size, together with the

above mentioned symptoms, the diagnosis of strangulated hernia may be made with almost absolute certainty. Another clinical symptom, which until quite recently received too little attention, is the presence of albumen in the urine. If the urine was free of albumen before strangulation occurred, it will be present after the intestine has been incarcerated for a short time, increasing according to the duration and severity of the constriction. Thus the quantity of albumen in strangulations which can be reduced by taxis is much less than in cases which require operation.

The question in all cases of strangulation, acute or not acute, which confronts us is: What treatment offers the best prognosis for the patient? Doubtless taxis, primarily. But the mortality following herniotomy has been greatly reduced since the introduction of antiseptis and asepsis and also by early operation. Though some surgeons now recommend operation in each individual case, I should always try taxis first, except in cases where the conditions contra-indicate this treatment. We have no exact statistics for reference in this matter. Should the taxis be successful the patient is almost well as soon as the rupture is reduced, and can fulfill his daily duties without being confined to his bed. We also avoid exposing him to the danger of prolonged narcosis which must never be underestimated. Beyond cavi, narcosis in cases of operation for strangulated hernia is very dangerous.

The circumstances under which taxis is contra-indicated are the following: great tenderness and pain in the region of the opening, redness of the skin, collapse, and increase of all the other symptoms; also, if the tumor, having for some time been very tense, suddenly becomes soft and collapsed. The last symptom would lead one to suspect perforation of the prolapsed gut. In former times many internal remedies were resorted to in connection with taxis; such as opium, morphine, and other narcotics; also tobacco clyster, cathartics, hot poultices, cold application and douches. These therapeutic measures are usually but a waste of time, with perhaps the exception of a high injection of lukewarm water. The intestine thus filled will sometimes by its own weight draw back the prolapsed loop. The greatest assistance in taxis is derived from general narcosis, providing, of course, that the patient is still in fair condition; that is, if he is not yet almost pulseless, or so collapsed that a few drops of chloroform would kill him. Therefore, a patient should never be anesthetized unless the surgeon is fully prepared for operation and has complete consent thereto. The technic of taxis is as follows: After the patient has been placed upon the table, as before suggested, the operator, standing at his right side, places the thumb and index finger of the left hand at the opening, and with the right hand seizing the lower part of the rupture, attempts first to pull out a little more of the intestine, and then begins pressing with the right hand, at first gently, then little by little with increasing force, so endeavoring to empty the bowel of its contents, and finally to reduce the prolapsed portion. If a general decrease of the tumor is felt, and a murmuring, gurgling sound is heard, taxis has been successful. The force applied by the manual reduction of a strangulated

hernia must be a moderate one, for it must be borne in mind that we are dealing with very tender and more or less inflamed tissues. The fact that the patient under narcosis does not feel pain should not mislead the physician to rough handling of these very sensitive tissues. A slightly inflamed intestinal wall may become gangrenous in consequence of severe pressure; or a partially gangrenous loop, which, perhaps, under careful handling might have recovered, may be perforated. Last, but not least, care must be taken, that by reduction *en bloc* internal incarceration be not produced.

How long may taxis safely be continued? It is extremely difficult to give a definite answer to the question of time, as much depends upon the general condition of the patient and of the involved tissues; of the duration of the strangulation, and whether many attempts have been made to reduce the rupture, either by the patient or other persons, before the arrival of the physician. However, considering the fact that early operation affords so much better prognosis than a late one, and thanks to the inestimably valuable work of our great master, Lister, which enables us to operate so much more safely than our ancestors, it is not advisable to delay the operation too long or to leave a strangulated hernia in that condition over night. Should the strangulation, while the patient is under narcosis, not yield to the first attempt at reduction, the operation should be performed without further delay; with the added reason that, under favorable conditions, a radical operation may be performed, thus saving the patient from a recurrence of the previous experience. That the operation must be attended by all antiseptic and aseptic precautions, I need not say, as there is no other way of operating to-day, let it be a question of laparotomy or the amputation of the first phalanx of a finger. These precautions may be fulfilled wherever we can obtain boiling water; and in every farm-house are fire-place and boiler utilizable for this purpose.

Now, a few words in regard to anesthesia. If the patient is narcotized for taxis, we proceed under these conditions. For this, ether is preferable to chloroform, first, because ether is less dangerous to the heart, and second, because an inexperienced assistant cannot do so much harm with ether as with chloroform. I always prefer local anesthesia for patients with low heart action and small and rapid pulse; for old people, especially old women with small strangulated femoral hernias. A little experience shows that a 4% solution of eucaïne or Schleich's solution is quite sufficient for local anesthesia. Those cases which are operated without the aid of general anesthesia show the best results.

We have two methods of operation for the relief of strangulation. First, external herniotomy—that is, operation without opening the hernial sac; and second, internal herniotomy, when the sac is opened. The first operation may be employed in case of a recent hernia, never before strangulated and for which a truss has not been used. In such, no pathological changes have yet taken place in the sac. This method is contra-indicated in all cases of inflammation; and also when a large portion of omentum is prolapsed, or after adhesions have formed between the hernial sac and surrounding tissues. Thus, the

sac need not be opened in cases where the strangulation has not occurred in the sac itself, and when it is possible to ascertain the condition of the contents of the sac. The great advantage of this method is that after the strangulation has been released we have practically to deal with but a skin wound, and the danger is thus greatly diminished, since the peritoneal cavity has not been opened. This is of signal value if one is not able to operate amidst proper surroundings. And yet, striking as in this advantage, one should positively not fail to open the sac, if after opening the fascia propria the contents do not yield to the gentlest pressure.

The technic of external herniotomy is as follows: After the field of the operation has been made aseptic by brushing it with hot water and soap, followed by washing with bi-chloride solution 1-2000, and alcohol, the skin incision is made in the direction of the rupture, extending the hernial opening from 1 to 1½ inches. This opening with a part of the neck of the sac must be exposed to the eye of the operator. After division of the underlying connective tissue, we come to fascia propria. This is a bag enclosing the hernial sac and consisting of fibrous, connective and muscular tissue in the inguinal hernia. The upper part near the opening must be lifted between two thumb-forceps and opened to bring the sac free to the eye. In favorable cases the place of the constriction can now be felt by the finger. It is not an absolute necessity that the opening be the constricting part; but we very frequently find bands of connective tissue or of fibrous character which surround the sac like a thread or a sling. All these constricting strings are best divided on a grooved director, and if the opening is the incarcerating part, it is split in the same way, in case we fail to dilate it with the finger. The rupture should then be reducible by a very slight pressure. If this is not possible the sac must be opened. The wound may be closed by suture for which purpose silk-worm gut is the best material. After a week's duration the wound usually has healed by primary union and the patient may leave the bed.

The technique of internal herniotomy differs from that of external herniotomy in inguinal hernia in so far that the skin incision is made parallel with Poupart's ligament beginning from the internal ring along the inguinal canal and extending the external opening for about 3 cm. In a femoral hernia the incision is identical for both operations. I give preference to vertical opening directly across the highest point of the protrusion. The incision for operation of strangulated inguinal hernia permits, in selected cases, radical operation in connection with that for strangulation. The few veins found in dividing the skin and the underlying cellular tissue can be clamped and ligated before cutting. Then the aponeurosis of the external oblique is reached and is easily recognized by its bluish color. The next step is to introduce a grooved director through the external ring under the aponeurosis and to split it up with the probe as a guide, so saving the underlying muscular fibres from injury. The fascia propria, that is, the surrounding tissue of the hernia sac, is now exposed. A little thereof is taken in a thumb-forceps and nicked with a pair of scissors. Then a grooved director is introduced into the small

opening, and the entire membrane is divided in the same direction as the skin incision. This exposes the hernial sac, which is a smooth serous membrane, somewhat uneven on its surface, and somewhat vascular. The next step of the operation is opening the sac. This is done by lifting a fold with thumb-forceps and making a flat incision with a scalpel at its base. The hernial fluid will now escape from the sac. Again, a grooved director is introduced into the opening, and the sac carefully opened. It is not advisable to extend the incision down to the hernial opening, but to leave about one-half an inch of the sac intact. Fresh adhesions between hernial sac and intestinal wall can, as a rule, be freed by the grooved director or by the finger introduced into the sac. Old adhesions are not, as a rule, very extensive. If they cannot be dissected free with Cooper scissor, it is better to leave a part of the hernial sac attached to the hernial wall, and not to risk injuring it. The prolapsed intestine is now examined for any evidence of beginning necrosis. In case any is present, especially at the constricting ring, great care must be taken in handling the loops, especially as regards any traction thereof. In case of the absence of any further abnormalities within the hernial sac which continue the strangulation, we try to find the constricting ring. For this purpose, the left hand, by means of thumb-forceps, draws the hernial sac toward the operator, who introduces the right index finger into the neck of the sac, where it will feel a fold, ring shaped, and mostly sharp edged. This constriction is the place of incarceration. Two methods of dilatation of the constriction have been employed. In the first method the right index finger is introduced into the constriction, the left hand leads a blunt-pointed tenotome into the ring along the rear side of the index and rotates its sharp side to the constricting tissue, while the index finger pressing against it, makes the incision. If one incision be not sufficient, a second one is made at about one quarter of an inch from the first.

The other method, which is now usually practiced, consists in splitting the constricting tissues from without, inwards. We divide the rest of the sac down to the constriction, and lifting it by a sharp hook or forceps, cut into it with a small scalpel. This method seems to me preferable because of the facility it offers in controlling hemorrhage. After another careful inspection of the prolapsed gut for any symptoms of necrosis, and after emptying the contents of the intestine back into the abdominal cavity, the reduction of the hernia may be completed. In case of failure, another undivided constriction or an intestinal twist must be sought and remedied. After ligating the hernial sac the wound is closed. For greater safety a strip of iodoform gauze is left in the lower angle for drainage; this strip may be removed one or two days later. The patient will soon pass gases and his bowels will begin to move. None but fluid diet should be given for about a week. In doubtful cases, whether a suspicious-looking intestine may develop necrosis or may recover, it is wise to leave the loop outside the abdominal cavity for twenty-four hours, until its fate can be decided. To prevent its slipping back, a strip of iodoform gauze may be drawn through an

opening in the mesentery and the entire wound covered with sterilized gauze. It is surprising how a desperate-looking gut, with almost black discolorations, will recover the following day and regain its elasticity after blood circulation is restored. Even the most experienced surgeons cannot always decide at once whether an intestinal loop will become necrotic or not.

What are the advantages, first to the patient, and second to the operator, if he waits a day before finishing the operation? The patient is released by a short operation from his strangulated rupture, and the immediate danger to life is removed; he has the opportunity to recover from the severe shock from which all these patients suffer more or less, and should it unfortunately happen that gangrene sets in, and intestinal resection anastomosis become necessary, he is in better general condition for this operation than he was the day before.

And as to the practitioner? After he has fulfilled his chief duty by attempting to save his patient's life by immediate surgical interference, he has the chance to obtain the assistance of an experienced surgeon if another and difficult operation must be performed. Now arises the important question, what shall the practitioner do if he finds a gangrenous and perforated intestinal loop? If the gangrene is very limited and the perforation not exceeding the size of a five-cent piece, the opening may be closed by interrupted silk sutures, inverting the edges of the wound to the lumen of the intestine, preventing necrotic tissue from entering the free abdominal cavity, and allowing it to pass through the intestine. Leave the loop outside the abdominal cavity and dust it with iodoform powder. After careful disinfection of the entire wound an aseptic dressing must be applied. The next day, if the gangrene does not show further development, the loop may be reduced and the operation finished. In those desperate cases in which gangrene is extensive and perforation has occurred in several places; when the whole hernial sac is phlegmonous and filled with fecal matter, nothing but drainage and disinfection with carbolic acid can be of any avail. When the intestine must be attached to the thigh by several stitches, the lumen of the ascending part should be maintained and drained by a wide calibre rubber drain; or if no drainage tubes be at hand, iodoform gauze must be placed in the gut to conduct its contents out. Patients in this condition are usually so collapsed and so nearly pulseless that any extensive interference for the time is naturally forbidden.

In closing this paper, a case may be cited to show how much harm may be done in strangulated hernia, by submitting the patient to a prolonged operation and prolonged narcosis.

About two years ago, a man, 28 years of age, came to a hospital in this city with a strangulated right inguinal hernia. Strangulation had occurred in the forenoon and the operation was performed at about 4 P. M. of the same day by the house surgeon of the hospital with the assistance of the attending surgeon. The intestine did not show symptoms of beginning gangrene, and could be easily reduced after the sac was opened, and the radical operation was performed. The duration of operation was one and

three-quarter hours, and though the patient was in excellent condition when he entered the hospital, he died three hours later from shock. This case is mentioned to emphasize the fact that the element of possible shock must never pass unheeded. As a rule, however, with due care, and following ordinary surgical principles, strangulated hernia is within that list of surgical ailments which may be viewed optimistically.

This view-point is based upon study and experience, which leads me to submit:

1. That strangulated hernia is entirely within the scope of those conditions which the general practitioner can treat.
2. That not more than a fair modern surgical education is required.
3. That no rarely-used instruments are needed.
4. Strangulated hernia is so exceedingly frequent that every physician should inform himself on the technique of its treatment.

5. That the simple procedures I have endeavored to make plain yield successful results in the vast majority of cases.

Throughout this little sketch I have striven to avoid encumbering my effort with reference to literature on strangulated hernia. The extensive works and innumerable journal articles on the subject have attained colossal dimensions. He who desires to do special work in this department must naturally study this immense literature; and I can promise him that he will be amply rewarded therefor.

Lest, however the impression be conveyed that I would operate on all cases of hernia, I must lay stress upon the fact that there are conditions, such as advanced age, where a well-adapted truss will suffice to attain the desired ends. The adaptation of a truss, however, is not so trifling a matter as some instrument-makers would have it appear. Indeed, in many cases the injudicious selection and application of a truss can, and often does, precipitate the danger which makes capital surgical intervention imperative.

In conclusion, I beg to say that if this effort serves as a guide to but one of my junior colleagues, leading him to save the life of his next case of strangulated hernia, my purpose will be fully attained.

On the lesions of the Central Nervous System Consecutive to the Elongation of the Peripheral and Cranial Nerves. G. Marinesco, (*Gaz. Heb. de Med. et de Chirurg.*, March 28, 1901. 48 me. Année, No. 25.) At a meeting of the Société de Biologie, held March 23, 1901. Marinesco reported the results of stretching the hypoglossal and sciatic nerves in a dog. The author found that in the neighborhood of the point of application of the stretching force, the myelin was fragmented and converted into large bulbs or presented granular degeneration. The axis cylinder was more or less altered and the nuclei of the sheath of Schwann multiplied. If the compression exercised in the neighborhood of the elongation is very marked the areas of degeneration are found deep in the nerve as well as in the superficial portion. The changes in the nerve cells are in relation to the degree and duration of the stretching force. When the traction is slight the cells present a slight swelling accompanied by a very moderate dissolution of the chromatic substance. If the stretching force has given rise to traumatic degeneration, the corresponding changes in the nerve center are more marked and the chromatic substance may be entirely dissolved. [J. M. S.]

THE SANATORIUM TREATMENT OF TUBERCULOSIS.

By ARTHUR J. RICHER, M. D.,
of Montreal.

Director of the Laurentian Sanatorium Ste. Agathe des Monts, P. Que.

In 1859 Brehmer, of Goersbersdorf, laid the foundation for the hygienic or instrumental treatment of pulmonary tuberculosis, not, however, without meeting with some opposition from the government of the Silesian province before the first sanatorium was constructed. The treatment as first conceived by him was most simple. He believed outdoor life, exercise and a liberal diet were the essentials for the cure, but he also held the belief that the climate in the vicinity of Goersbersdorf was a specific one, being supposedly immune from the disease, Dettweiler, who had been a patient, and later assistant physician to Brehmer at Goersbersdorf, opened another sanatorium at Falkenstein in 1876.

Dettweiler held somewhat different views and modified to some extent the treatment which had been originated by his teacher, recommending rest instead of exercise in the treatment of pulmonary tuberculosis. It is needless to say that these two pioneers had to face the harsh criticisms of the whole professional world for nearly twenty years before the medical men took up the subject and discussed it in a fair manner, as the prevailing opinion at that time rather pointed to the belief of incurability. Towards the end of the struggle these two phthisio-theapentists had created a small school, which soon added to its number of adherents, until now we find the field of phthisio-therapeutics as an established department of medicine in every civilized portion of the globe.

The essentials of the sanatorium treatment as understood and practiced at the present time by the phthisio-therapeutics the world over, may be summed up in the following terms: **Rest, Outdoor Life, Overfeeding, Medical Supervision.** For the sake of convenience we shall consider each subdivision of the hygienic or sanatorium treatment separately in the order named:

Rest.—This should be an absolute term, understood as such by all serious-minded, well-intentioned medical men who are looking forward to the permanent recovery of their phthisical patients. In incipient cases **rest, absolute rest**, must be enjoined. A score of personal observations might be cited of patients giving promise of complete recovery, who have simply murdered themselves with the mild (!) exercise prescribed for them.

I have very little hesitation in making the statement that the time is not far distant when the term "rest" will mean the recumbent position as applied to the treatment of incipient pulmonary phthisis. I have kept patients in bed, in the open air, during the incipient stage of the disease, for three, four and five weeks, at the outset of their treatment and always with most beneficial results.

I recall one instance of a male patient gaining one pound in weight every day during a three weeks' stay in bed, and ultimately making a most perfect recovery in three and a half months.

The *rest-cure* as practiced at the present time is in a semi-reclining position in a steamer chair, or an adjustable invalid's chair, out of doors. The patient is made as comfortable as possible with the aid of

cushions, rugs, etc., and in winter a hot soapstone is placed at the feet. Each sitting of two to three hours is interrupted by the ingestion of food, and a short walk of forty to fifty steps on the veranda.

The term "rest" should imply even more. A wound on any part of the body is set to rest by protective bandages. The wound in the lung should also be protected as much as is possible. Hilarious outbursts, loud and excessive talking, singing, forced expiration and inspiration, or any attempt at chest expansion, until there is evidence of arrested disease, are bound to be injurious. In a like manner emotional reading, sexual reflexions, or indulgences, however mild, are to be avoided.

Smoking and the unwarranted use of intoxicants, as well as games of an exciting nature, should not be allowed. Anything that will increase the respiration or pulse rate is going to interfere with speedy recovery by irritating the wound which is attempting to heal by resolution.

Outdoor Life.—In the summer time not less than ten hours, in the winter season not less than six hours, should be spent in the open air. In the Laurentian Mountains our patients put in an average outdoor stay of twelve hours in the summer and eight in the winter, inclusive of inclement weather.

Patients sleep with their bedroom windows open both summer and winter. During the extreme cold weather a hot soapstone is usually placed at the foot of the bed, thus keeping the feet and body warm with comfortable bed clothing, while the head is kept quite cool, the patient constantly breathing fresh air, practically continuing his outdoor life while sleeping.

Gradually accustoming your patients to this open air method of living makes them extremely resistant to cold, and increases the power of food assimilation and metabolism.

The following summary of meteorological observations will give you some idea of what outdoor life means in the Laurentian Mountains, where is situated the now well-known resort and sanatorium of Ste. Agathe des Monts:

—1900.—

Min. temp.		Max. temp.		Mean. temp.		Days of Sunshine.		Rainfall.	
January	July	Jan.	July	June	October	June	October		
—17°	82°	7.88°	62.08°	20	18	3.6 in.	1.13 in.		

The fact that open air life in favored resorts is not hindered by inclement weather, and the further well-known fact that the outdoor life is practically carried on throughout the night as well as the day makes the possibility of a similar treatment being carried out at a very moderate altitude anywhere, if one can only be assured of a plentiful supply of pure air. The very good results obtained in the Laurentian Mountains, where the elevation is quite moderate, varying from 1,200 to 1,700 feet above the sea, should encourage every physician to seek suitable resorts as near the home of the patient as possible.

We know from experience that the permanent cures are those obtained in home climates.

Overfeeding.—This does not necessarily mean "gavage" or "forced feeding," the average patient does not require these extreme measures, as the change to a suitable climate with health-giving and restful surroundings usually develops in the individual a voracious appetite. The northern altitudes particularly enhance food assimilation, and the winter season in northern climates is remarkably stimulating in this direction.

Food must be given at frequent intervals, as digestion is much more rapid under this regime of life. Before rising the patient should be given some light liquid food or some fruit, hot milk, gruel, coffee and cream, etc., the choice being left to the physician, or guided by the desires of the patient. The patient is then allowed to rise and dress and take his regular breakfast at an hour or so after the breakfast of awakening. The regular breakfast should be varied, but oatmeal or some other cereal food should be taken daily. Honey, hot rolls, cornmeal cakes, fish, either smoked or fresh, lamb cutlet or a small steak, eggs in any form, sometimes bacon, toast, coffee, milk, etc., should be varied and used at breakfast time.

Between breakfast and the midday meal (which should be the heaviest meal of the day) a small luncheon should be taken, consisting of biscuits and cocoa. Tropon chocolate or tropon biscuits, cold milk with somatose, one or two raw eggs, broth or beef tea with buttered bread, etc. This intervening lunch should be varied each day as much as possible, yet when patients can be made to ingest one, two or three raw eggs without producing nausea, it is preferable to keep on giving the eggs daily.

The midday meal should be taken at one o'clock and should invariably begin with a rich consommé not too highly seasoned, in which one may add a small teaspoonful of Tropon or Somatose. This should be followed by a light entrée of fish, or some cold meats, or daintily made dishes, followed by roast meat, such as lamb, fowl, beef (underdone), etc., with large quantities of vegetables, such as cabbage, potatoes, lettuce, spinach, asparagus, green peas, beans, etc. Desserts are not considered necessary, yet such a meal requires relieving dishes, so that ices, milk puddings, light cake and preserved as well as fresh fruit may be partaken of. Fruit should at all seasons be made use of in the diet of a consumptive, unless the condition of the bowels should be a contraindication. Between the midday meal and supper a light lunch such as the one outlined for the forenoon should be partaken of. The supper should not be a hearty meal. Some hot or cold preserved fruit. Before retiring at nine o'clock some hot milk or an egg-nog usually procures a restful night. The supervision of the cooking should not be neglected by the physician; in fact, the successful phthisio-therapist is the man who, though roughly, understands the culinary art, and devotes a great part of his time to supervising the preparation of the food his patients are called upon to ingest. Quite often a patient will come to the conclusion that overfeeding, or stuffing as he calls it, is going to ruin his digestive organs. You must

in such instances make use of your persuasive powers, and convince your patient that even if he should have no desire for food, his digestive organs will assimilate all he can ingest, even if he forces himself unto nausea. Impress upon him the fact that the digestive organs are more apt to become inactive if given but little to do, while the stomach itself possesses the indisputable privilege of relieving itself speedily when overloaded, which seldom happens.

If it becomes necessary to resort to forced feeding, the greatest firmness is required on the part of the physician, in order to confirm his earnestness in helping the patient in the battle for life. After the stomach tube has been used a few times the patient usually realizes that he can ingest his food quite well without it, and he usually becomes the hero. Persuasion and firmness, however, usually render it unnecessary to resort to extreme measures.

A palatable combination of proteids and carbohydrates, with a small quantity of alcohol, given between meals, will, in the majority of cases, favor the assimilation and storage of hydro-carbons contained in the usual diet.

Medical Supervision.—This is the keynote to success in the treatment of tuberculosis. It is this supervision which has carved the name of victory in the field of phthisio-therapy. It must, however, be constant. The physician must be the friend as well as the adviser of the consumptive. He must study the peculiarities of each patient, and individualize his treatment, if the régime may be called such. In appalling numbers the victims of this lack of supervision are to be found in open health resorts. To-day you may be called to attend an individual who has an exacerbation after having been for a long walk, a bicycle ride, a canoe or boat outing, either paddling or rowing; to-morrow you may be summoned to the bedside of a young mother with an extension of her lung lesion through having had to sacrifice herself at the altar of devotion attending her child during an acute illness; the next day a young lady seeks your advice: she has had a slight rise of temperature following a prolonged drive, having returned home in an exhausted condition, and in the course of a few weeks a new focus develops under your observation. How many instances one could recite of the fatality of this lack of medical supervision, which is nowhere else so absolutely necessary as in the treatment of pulmonary tuberculosis.

Medical Treatment.—Outside of a few symptomatic indications drugs are seldom of any real value in the treatment of pulmonary phthisis.

In fact, the patient who is made to follow the hygienio-dietetic treatment exclusively is the one who improves most speedily. Where indicated strychnine in doses of 1-30th of a grain has proved very useful. Creasote still remains the most reliable internal antiseptic in tuberculosis. It should, however, be used in the form of creasote water, nearly to saturation, and both the creasote and water must be strictly pure, as otherwise disastrous results are bound to follow its administration. The doses exhibited in creasote water may safely reach 30 drops three times a day, but should not be long continued. Recent hæmoptysis, as you know, is

a contraindication to the use of creasote or any of its derivatives.

The fever of tuberculosis should invariably be treated by rest in bed. The use of antipyretics should not be encouraged. If antipyretics are used at all, the chosen one should be given from one-half to one hour preceding the time of the expected rise of temperature.

Cinnamic acid and cacodylate of soda, of which we have heard much lately, are apt to be recommended.

One might enumerate by the dozen the different remedies which have been advocated for the treatment of phthisis. Let me tell you that very few of these have ever proved beneficial, while we have proof positive of the dangers of supermedication in the treatment of this disease.

The *cough* is usually controlled by the use of codein, heroin or diorin. The *night sweats* usually disappear with increased nutrition. They can be controlled if necessary by the use of atropine (1-80 gr.) or camphoric acid (20-30 grs.).

The hemoptysis when profuse is always a dangerous complication. Absolute rest in bed in semi-reclining position must be enjoined. For twenty-four hours after a hemorrhage the movements of body, limbs or head must not be allowed; even whispering must be avoided by the patient. Ice packs to the chest, with a hypo of morphine sulph., 1-4 grain, and atropine, 1-75 grain, in combination, will as a rule hasten the formation of the sealing clot.

According to the severity of the hemorrhages, rest in bed must be enjoined for sometime, varying from two to fifteen days after the last trace of blood has disappeared from the sputum.

Conclusion.—We usually judge of the efficiency of to the inevitable conclusion that the hygienic treatment produces.

Looking into the records of the older institutions, such as Goerbersdorf and Falkenstein in Germany, giving a percentage of permanently arrested disease in over 60 per cent. of cases treated, and also taking into consideration the very excellent results obtained at the Adirondack Cottage Sanatorium, with a percentage of over 70 per cent. of cures, we must come to the inevitable conclusion that the hygienic treatment has definitely established its superiority. I have quoted the two oldest institutions in Europe (over thirty years) and the oldest institution in America (over twenty years) as the results obtained during a long period are far more convincing. I do not wish to enumerate the different institutions in America which are now doing similarly good work and obtaining results quite as good, as such would encroach upon your time.

Being favored by many ideal health resorts in different parts of the North American Continent, one cannot but ask why more sanatoria are not in active operation. The reason is to be found in the fact that the erection and maintenance of such institutions is largely a social problem, and the public has not yet been aroused to the needs of the population which is being decimated by this disease.

A most important factor in sanatorium treatment is the education given to the patient which will allow him to lead a more hygienic life at home, as

well as graduating him as a teacher in the prevention of disease.

It is a well known fact that when pulmonary tuberculosis becomes arrested, the disease cannot be considered as positively cured unless good health has been enjoyed for at least eight years after the arrest of the disease. Thus the necessity of a practical hygienic education becomes imperative, and this can only be obtained by a sufficiently long stay in a supervised institution.

The time is not far distant, I hope, when every city in this Dominion will have its sanatorium at as short a distance as possible, with its rural probating as well as isolating home in the immediate vicinity of its suburbs.

ORTHOPEDIC TREATMENT OF DEFORMITIES AND DISABILITIES RESULTING FROM DISEASES OF THE NERVOUS SYSTEM—SPECIAL REFERENCE TO TENDON TRANSPOSITION.*

BY B. E. MCKENZIE, B.A., M.D.

Surgeon to Toronto Orthopedic Hospital; Orthopedic Surgeon, Grace Gen. Hospital; Asst. Prof. Clinical Surgery, Ont. Med. College for Women, Toronto, Canada.

On reviewing the cases that have presented themselves for orthopedic treatment in the last thirteen years, I find that nearly 20 per cent. of all patients seeking advice do so because locomotion and symmetry are interfered with by deformity or disability arising from some affection of the nervous system. The proportion is about equal to that of cases arising from bone or joint disease, but smaller than that due to congenital deformities or defects.

Of the various nervous affections, acute anterior poliomyelitis is much the most common in producing the conditions for which alleviation is sought. The affection is marked by atrophy of the muscles involved, by altered electrical reactions, diminution or loss of the reflexes, and by a peculiar distribution of the paralysis according to function, rather than anatomy. This last feature is an interesting one, and has an important bearing, as will be seen, upon the treatment of these cases.

Joint Equilibrium.

The normal condition of a joint implies that the muscles exercising control shall be able to maintain a balance. If at the knee the quadriceps femoris be reduced in power or completely paralyzed, its antagonistic group, the hamstrings, will so disturb the balance as to make flexion easy and habitual, while complete extension will be difficult or impossible. Under these circumstances the condition of flexion soon becomes permanent and contracture of the hamstrings results, so that we have a fixed deformity. (It is important to note that the word "contracture" here used is meant to imply a permanently shortened condition of the muscle.) It is seldom, relatively, that any muscle or group of muscles thus affected is completely paralyzed. There is generally some degree of power left, and quite frequently the muscle is only slightly disabled. These effects, also, as will be seen, have an important bearing upon the treatment.

* Read at the meeting of the Canadian Medical Association, at Winnipeg, August 28th to 31st, 1901.

If the peronei muscles be partially or completely paralyzed, those muscles passing to the inner border of the foot draw it inward and deformity is gradually produced; or if the anterior leg muscles be partially or completely disabled through paralysis, then the back group, acting through the tendo Achillis, gradually bring about a condition in which the heel is kept drawn up and the anterior portion of the foot is pointed downward, a condition known as talipes equinus. If the quadriceps extensor of the thigh be disabled, the hamstrings tend to produce permanent flexion at the knee; if the glutei have less than normal power, the flexors of the thigh will tend toward its permanent flexion upon the pelvis, and in a similar manner through disablement of other groups of muscles various other deformities may be caused.

Mechanical Treatment.

Until comparatively recent years, the only aid given to these patients was afforded through the use of appliances, generally consisting of steel braces strapped about the legs and attached to the boots. Both in books and in practice even at the present time this method of dealing with weakened limbs is far too common.

The constant use of braces and straps tends to prevent a development which might otherwise be induced. While the use of braces cannot be given up in all cases, yet it may be said that their employment has been quite too general. They may be frequently employed with advantage, especially at night when the patient is in bed. It is then that the part is allowed to assume the position of deformity, the knee to be continuously flexed and the hamstrings are permitted to become contracted, or the anterior part of the foot is allowed to drop downward and the tendo Achillis to become permanently shortened. The wearing of a simple nightbrace that will hold the leg or foot in position during the hours of recumbency, is much less objectionable than it would be when the patient is moving about. It does not prevent development of muscle, it is not seen by the public, and its inconvenience is reduced to a minimum.

Some Peculiarities of Infantile Paralysis.

There are some peculiarities of acute anterior poliomyelitis which will bear special study because they afford indications for its rational treatment.

The paralysis is not general, but local. Mary Putnam-Jacobi, in Pepper's "System of Medicine," shows that in thirty-seven cases the paralysis was distributed as follows: Left lower extremity in thirty-four cases; right lower extremity forty times; right upper extremity and left lower extremity twenty-three times; all four extremities seven times; both upper extremities three times; both lower extremities twenty-three times; left upper and lower extremity twice; right upper and lower extremity once; right upper and left lower extremity three times, muscles of trunk and abdomen once.

It will be noticed that the lower extremities are much more frequently involved than the upper. Here is a feature of the disease specially worthy of consideration in view of treatment. The difference of function between the upper and the lower extremity is marked. In order that the hand and arm

may be of service, it is necessary that the fingers should be capable of considerable dexterity. They need the deftness which can finger a musical instrument, tie a knot, grasp a handle, hold and use a needle, etc. The upper extremity, which cannot approach in delicateness of function to this ideal, falls proportionately below its requirements. The lower extremity, on the other hand, serves comparatively well its purpose if only it can be a secure and substantial post to bear the body weight. The further it can go beyond this in adding to the activity of the individual the better. The comparative coarseness of function of the lower extremity, however, makes it much more amenable to treatment in the manner which is to be indicated in this paper than is the upper extremity.

It is further noticeable that the paralysis, even in a single extremity, is not general, but is limited to muscles functionally related. In the upper extremity the supinator longus generally escapes in spite of the fact that all the extensor muscles of the forearm are paralyzed, and though these are supplied by the same nerve; in the lower the sartorius generally escapes, though the quadriceps femoris be greatly disabled. On the other hand, the supinator longus is generally affected along with the deltoid, biceps, and brachialis anticus, with which it is functionally associated. The tibialis anticus is generally paralyzed in connection with the quadriceps extensor. These muscles are supplied by different nerves, but are associated in extension movements of the leg in walking.

In the lower extremity the peronei muscles situated at the outer border of the leg and foot, and employed to move the foot outward, are most frequently affected. Next in frequency is the posterior tibial and then the anterior thigh muscles, and least frequently the posterior thigh muscles. Rarely an entire extremity or a large group of muscles may be permanently paralyzed, but the paralysis is sometimes restricted to a single muscle.

The definitely localized paralysis and atrophy point to the importance of massage and electricity being applied early to stimulate the nutrition of the affected muscles. If contracture has been allowed to occur, section of the tendons of the contracted muscles and immediate replacement of the deformed member are indicated. Such replacement must be followed by the use of mechanical means to prevent recurrence, and under such circumstances results which are most gratifying are frequently obtained.

A further study of the mechanical conditions present affords a basis for a novel and bold, but quite a rational and effective, method of treatment. The conditions of the foot when the calf muscles are paralyzed and the peronei escape, will serve to explain the method of treatment here referred to.

Muscle Transposition.

The muscles causing movement at the joint should maintain an even balance among themselves, but in the case where the calf muscles are paralyzed and the peronei active the heel will drop down, the outer border of the foot raised up, and the foot drawn outward.

No surgical intervention can add to the sum total

of the power manifested by the muscles producing movement at the ankle, but a readjustment may be made as to establish a more even balance. The effect of the peronei when unopposed is positively harmful and if nothing better can be done their tendons should be cut so as to permit correction of the deformity. This procedure would further lessen the sum of power possessed by the muscles at the ankle; hence a transposition of the peronei is made. The tendo Achillis having been freely exposed, and the peronei tendons having been cut subcutaneously in front of and below the external malleolus, these latter are reached at a point where they are nearest to the incision made over the tendo Achillis and are drawn from their sheath. The proximal segments of the peronei tendons are now inserted into the tendo Achillis as close as possible to the os calcis. It is generally advisable to shorten the tendo Achillis before the peronei tendons are sutured as here advised. If each of the peronei tendons have its proximal segment split, it can be introduced in a fork-like manner along with the split portions of the tendo Achillis, so as to make a very strong union. In suturing these parts together the posterior extremity of the os calcis should be pushed as high up as possible and the peronei tendons should be drawn down so as to make the distance between the origin of the peronei and the new insertion as short as possible. The union which takes place under such circumstances is nearly always without failure or defect. Circumstances permitted the cutting down upon such grafted tendons a few months ago when the splicing was found to be most complete, a strong union having been formed at the point where the tendons had been sutured together.

When the healing is complete, it will be noticed that the power of the active unparalyzed peronei, which before were harmful in their action, is transposed so as to permit them to pull upward at the insertion of the tendo Achillis. Thus, without lessening the sum total of power manifested at the joint, its action has been so rearranged as to establish a better balance of the foot, and to change its position so as to bring it more directly and effectively under the body weight, thereby improving its function.

History of Cases.

In a similar way numerous other transpositions may be made with signal advantage to the usefulness of the affected extremity. I shall report briefly a few cases to illustrate some of the many varieties of transposition which may be made.

Case 1.—December, 1892. H. R., a boy, aged 11; infantile paralysis; history incomplete; lame from childhood, but not from the time when he first learned to walk. Both legs affected; right leg, in all its parts, is smaller and weaker than the left, but the paresis is more marked in the internal and extensor muscles of the foot. The gastrocnemius, soleus, and posterior tibial muscles are powerless. The flexor longus digitorum, the flexor longus hallucis, the tibialis anticus, and peronei are active. The latter muscles are displaced one inch forward from their natural position behind the external malleolus.

Operation.—An incision was made extending three inches directly over the tendo Achillis, which was

found to be a firm fibrous cord about the size of a lead pencil. The tendon was split, the incision being continued down to the os calcis. The tendons of the peronei were cut subcutaneously, and the proximal segments having been drawn from their sheaths, were stitched into the tendo Achillis as close as possible to the insertion into the os calcis. The tendon of the flexor longus digitorum was reached by dissection from the first incision, cut and sutured with the peronei. Healing was satisfactory, and three months afterward walking was much improved. He has increased power of raising the heel, though not sufficient to enable him to sustain his weight by raising the heel from the floor and balancing upon the anterior part of the foot. A properly constructed boot was made supporting the inner border of the foot. He wears no brace, and walks much better than formerly.

FIGURE 1

Case 2.—R. M., aged 14; had a severe attack of anterior poliomyelitis in infancy, greatly disabling both extremities. The right foot was drawn into strongly marked valgus, as shown in Fig. 1. The quadriceps extensor of the left side was so completely disabled as to make it necessary to place his hand on his knee in walking. Otherwise the knee would become flexed and the body weight coming upon the limb cause him to fall. Various other groups of muscles were so affected as to make it impossible for him to walk more than a couple of blocks at a time, the disability increasing as his age and weight increased.

Feb. 21st, 1901, the scaphoid of the right foot was removed, the cartilages of the head of the astragalus and of the cuneiform bones were completely cut away so as to leave a fresh bleeding surface of bone. The gap was closed up by adducting the anterior portion of the foot, and the freshly-cut surfaces were brought into intimate contact, purposing to obtain a synostosis.

The tibialis posticus being completely paralyzed, and the extensor hallucis being left unaffected, and acting with such vigor that it dislocated the great toe dorsalward when an effort was made to dorsiflex the foot, the tendon of the former muscle was cut by an open incision two inches above the tip of the internal malleolus, and the distal segment of the

tendon, being pulled from its sheath, was carried up in front of the malleolus and sutured into the split tendon of the extensor hallucis. The result in improving the position of the foot may be seen in Figs. 1 and 2. The result in improved function is just as satisfactory as the improvement in appearance. The strong extensor which before was able to dislocate the toe upward can do so no longer because its force is expended partly in adducting the foot and raising its inner border.

FIGURE 2

May 2nd. In the same patient, who was obliged to place his hand on his knee in walking because of the disability of the quadriceps extensor to maintain extension, the sartorius was cut from its insertion and sutured in just above the patella. An incision five inches long was made midway between the patella and the tendon of the sartorius. The sartorius being found an active muscle, but inefficient, because of its insertion, to accomplish the work that is most needful for such a patient, it was cut near the insertion. The end of its proximal segment was drawn through a slit made in the fibrous structure just above the patella. The leg was kept fully extended for several weeks until healing had occurred. This patient was allowed to return home in five weeks after the last operation, able to walk further and with greater ease than formerly, he does not find it necessary to place the hand on the knee, and he can propel his bicycle with much greater force than he could before the operation. Time, development, and education of these muscles in their new role will greatly improve their efficiency.

Case 3.—September, 1899. C. M., aged 18. Left talipes valgus paralyticus. The extensor proprius pollicis and the peronei were found active, while both tibiales were greatly disabled. In this case the tendon of the extensor pollicis was cut, and the proximal portion transposed to that of the tibialis anticus and the proximal segments of the peronei were carried in front of the tendo Achillis and grafted into the tibialis posticus. The result was a very marked improvement.

Case 4.—H. C., aged 18, has right pes equinovarus and loss of power of extension of the left knee from anterior poliomyelitis. This young woman

walked with crutches constantly, except to move about in the house, which she could do by placing her hand upon the knee to prevent its giving way under her. The disability was increasing as the age and weight increased, and she had gradually become more dependent upon her crutches.

January, 1899, the sartorius was transposed as in Case 2 with a most gratifying result.

Enough cases have been related to illustrate this method of dealing with disabled and deformed extremities in such cases as are due to lack of balance in the muscle which control the foot and knee. It is a most satisfactory method of dealing with such affections of the lower extremity, but less helpful in the similar conditions which are found much less commonly in the upper.

Case 5.—One case may be related to show what is the practice at the wrist. January 2, 1900. M. A., aged 33, had hemiplegia when 19 years of age; has flexion at the wrist with contracture of the anterior muscles and tendons, and extreme pronation. The proximal segment of the flexor carpi ulnaris was carried around the ulnar border and grafted into the extensor carpi ulnaris, and the flexor carpi radialis was in a similar manner carried around the radial border and grafted into the extensor carpi radialis longior. Several bands of fascia and of carpal ligaments were divided subcutaneously and the hand dressed in a position of supination and extension. Healing was satisfactory, and there is some improvement in the use of the hand, arising largely from the fact that the wrist is no longer kept flexed, but remains in about a medial position. There is also greater readiness in letting go of an object on which the fingers have fastened. It is possible that greater gain might have resulted in this case if the tendons had been carried more directly to their point of action by putting the tendons through between the bones. There is also another step in the operation which might have been taken with benefit, namely, the pronator radii teres might have been cut from its ordinary insertion at the outer border of the radius and so transplanted as to pass between the radius and ulna to the same insertion at the tubercle of that bone. Much less opportunity has presented itself for operating upon the upper extremities, but so far as our observation goes the results are less satisfactory, not because the transposition could not be so well made, but because the requirements of the hand are so very different from those of the foot. Even in the hand and arm, however, much good may be effected by judicious tendon operations.

Before deciding what tendons to transpose and where to insert them, each case should be studied carefully with a view to determining exactly the effect produced by the action of each muscle both at its original and its new insertion. Either the distal segment of the tendon of a paralyzed muscle may be grafted into the uncut tendon of one that is active, as in case illustrated; or the proximal segment of an active muscle may be transferred to the tendon of one that is paralyzed, as in Case 3. There are some who advocate doing the former as frequently as possible and avoiding the latter, deeming it inadvisable to run the risk implied in cutting the

tendon of an active muscle. It should be noted, however, that such active muscle is not an efficient one. On the other hand, it would often be better to cut the tendon, even if it were only possible to destroy its action thereby, as in the case of the peronei when unopposed drawing the foot into a position of extreme valgus, or when the tibiales unopposed draw the foot into extreme varus and supination. After operating in both ways upon many cases since December, 1892, I do not regard the distinction as important.

If good judgment be exercised in the transposition made and care be taken in the operation, the success of the grafting is certain and always attended with improvement in function. The operation was first performed in 1882 by Nicoladoni and described in the *Archives of Clinical Surgery* of the same year. But little attention was paid to it, however, till Parish of New York employed the same principle in 1892, and described it in the *New York Medical Journal* of the same year. In recent years it has come rapidly into favor with orthopedic surgeons as a most valued means for improving the condition of many who suffer from paralytic disabilities.

Other methods of treatment employed are much more widely known and call for only a brief notice.

Mechanical means must often be employed because the disability is so great that the limb could not otherwise bear the body weight; but it should be carefully borne in mind that the use of braces retards the development of the extremity, and is therefore contraindicated if the limb can be kept in position and can perform its function fairly without aid. If the knee or ankle be so completely paralyzed as to be fairly described as the flail joint, then the subject of excision for the purpose of securing ankylosis should be considered. A leg without motion at either one or the other of its joints is much more serviceable than one that is extremely weak. Amputation because of paralysis should seldom or never be practiced, even in the most completely disabled lower extremity. The limb can better be employed as a core for a good mechanical appliance than can its place be taken by an artificial limb.

One important condition, and one often overlooked, is that of deformity arising from paralysis. Where this exists it is, in most instances, the surgeon's first duty to correct the deformity. In many cases the contractures resulting from the paralysis are insuperable obstacles in the way of progress, and it is not uncommon to find both children and adults unable to walk whose trouble is not due chiefly to the paralysis, but to the secondary deformity. One girl, four years of age, having spastic paralysis, the adductors being strongly affected, had never learned to walk because she could not carry one knee past the other. There were other troubles in the same child, namely, strongly marked flexion at the knees through contracture of the hamstrings and some deformity of the feet. Within three months of the time when all these contractures and deformities were overcome, so that the knees and feet could be kept in a correct position and the knees be fully extended, and the legs abducted so

as to make with each other an angle of 60 degrees, the child was able to walk about the house from one room to another.

Because of multiple neuritis following typhoid fever in a young woman of nineteen, and because of the deformity of feet and flexion of the knees resulting from contracture of hamstrings and calf muscles, she had not walked for nearly eighteen months. Rectification of the deformity was easily accomplished, and when followed up by physical training, including massage, her recovery was speedy and satisfactory. Without first getting rid of her deformities the power to walk could not have been restored.

Of other forms of disease of the nervous system concerning which advice is sought because the power of locomotion is defective, spastic paralysis is the most common. Section of the tendons of the muscles most affected, and pulling widely apart of the cut ends and their continued separation until healing has occurred, results in much benefit. A most important element in prognosis is found in making an accurate estimate of the patient's mental condition. More than half of these patients suffering from spastic paralysis are below par mentally. The better the mentality the more hopeful the prognosis.

Even cases of locomotor ataxia, pseudo-hypertrophic paralysis, and obscure forms of progressive muscular atrophy, seek advice because of defects of locomotion. It is only in rare instances and in limited measure that orthopedic surgery affords them any help.

On the other hand, neurotic patients frequently seek advice because of supposed disability of spine and of other joints. They are a class deserving of much judicious sympathy and are very amenable to treatment. A regularly constituted and well-equipped gymnasium is a powerful aid in the successful management of these patients.

Permit me to summarize:

1. Many patients who seek the advice of the orthopedic surgeon are suffering from some form of nervous affection—usually chronic.
2. When deformity exists it should be corrected.
3. When there is lack of balance at a joint an effort should be made to restore equilibrium.
4. Tendon transposition is an effective means to secure this end in selected cases.
5. Braces and splints should not be employed except in meeting the clearest indications.
6. Mechanical means wisely employed may do much to supplement the defective lower extremity.
7. Arthrodesis of a "flail" joint is often better than mechanical aid.
8. Amputation of a limb because of paralytic disability should seldom or never be performed.
9. The gymnasium is a powerful means of enforcing the discipline which is essential to successful treatment of so many neuroses.

MELANCHOLIA AND ITS TREATMENT.*

by GEORGE STOCKTON, M. D.,

of Columbus, Ohio.

Assistant Physician, State Hospital.

It would be impossible in a paper of this kind to attempt to give an exhaustive essay upon such an extensive subject. I will, if possible, give an outline of some cases as we see them every day in hospital duties, and very frequently in private practice. Melancholia has been defined as "A disease of the mind, due to the excitement of the depressive emotions." There is no doubt but what this disease was recognized and described by ancient authors. Burton, who wrote his *Anatomy of Melancholia* 300 years ago, a book made up largely of quotations, cites often from Galen, Hippocrates and other ancient authors. The immortal Shakespeare, in his writings, evidenced considerable knowledge of melancholia. In *Hamlet* some of the lines show an excellent conception of the disease. Heredity has been said to be a predisposing cause in this form of mental disease less often than in any other, yet Clouston states that he found a neuropathic history in 30% of the cases admitted to the Edinburgh asylum. All causes which tend to produce profound mental disturbance, by causing worry and anxiety, no doubt act as exciting sources. The disease is more common in females than in males; this has been attributed to the influence of the various diseases incident to menstruation, lactation and the numerous disorders of pregnancy. Ill health and chronic disease are no doubt prominent factors, as they tend to depress the mind. The stage of incubation is usually of long duration, unless it follows a severe shock or sickness of some kind. In simple melancholia, which usually precedes the more serious affection, the patient complains of weariness, insomnia, headache, loss of appetite; has indigestion, becomes irritable, and often has a sense of oppression and danger. It is a common symptom for the person so affected to think that they are to undergo some unique punishment, that their eyes are to be put out, that they are going to be placed in a vat of boiling water, burned up or something equally as dreadful. There is a loss of interest in their daily pursuits, they become indifferent to their family and closest friends. At this time they are able to give a tolerably clear account of their symptoms if desired. Food is either refused or taken reluctantly, the tongue is furred, the face presents an anxious look, and the eye loses expression. From this condition they often pass into the agitated form, hallucinations and delusions are manifest, they imagine that everybody is against them. A subnormal temperature is not uncommon; suicidal and occasionally homicidal symptoms make their appearance. We had a patient in the Columbus State Hospital at one time who jumped on the attendants or anyone who came near him; if they would take hold of him he would not make the least resistance; on being asked why he did this, he replied that he had no desire to injure any one, but that he attacked others with the hope that they might be provoked to

attack him and kill him, as he wished to die. This man afterwards made a complete recovery and remained so. Individuals sometimes have delusions so strong that they will permanently mutilate themselves. I recall two instances where patients have destroyed one of their eyes. The first on being asked why he did it, replied that his right eye offended him, and that he accordingly followed the advice of the Bible, which says: "If thy right eye offend thee, pluck it out. The second gave about the same reason, said that God told him to destroy the offending member. In the stuporous form of melancholia the patient usually refuses to talk, or is induced to do so with great difficulty. They will sit for hours and never move, sometimes this is due to a delusion, they think that God has commanded them not to stir, and that something terrible will happen to them or somebody else if they do. There is a fixed condition of the muscles, a catatonic rigidity at times, so that if you fix the hand in one position they will hold it that way for some time. The pupils are dilated, and the eyes have a staring expression; the skin presents a glistening appearance, and often a cyanotic hue. The odor from the breath is very offensive, and at times they will void their urine and feces in their clothing; they will hold their food and saliva in the mouth until their cheeks puff out and attention is drawn to it. This is, of course, due to defective inhibition and a suspension of will power. Hypochondria resembles melancholia and may lead to it. Every physician comes in contact with these cases in his practice; they persist in talking about their imaginary troubles until they become great bores. It has been said that a hypochondriac who is able to attend to his daily pursuits, is not disturbed in his family relations, and has no actual delusions, cannot be said to be dangerous to others. Cases of this kind need restraint when they lapse into melancholia of a dangerous character. The tendency to suicide in melancholians is met with quite often. If this tendency is in an aggravated form, they will resort to every possible plan to accomplish their purpose; this thought seems to be in their mind to the exclusion of everything else. They will throw themselves violently against a wall or the side of a door, and sometimes cut their heads badly; this is seldom successful, and is so painful that they rarely try it more than once. They will try to get hold of a knife or a piece of glass, a handkerchief or rope, or anything likely to accomplish their purpose. A short time ago we had a patient in the hospital who was the most persistently suicidal person I ever saw; he would wrap the sheet around his neck, and try to strangle himself; endeavored in every possible way to get hold of something by which he might destroy himself. The attendant had him in the bath room one day, by some means he got hold of a crooked nail; he pushed this through the walls of the chest, barely escaping the apex of the heart. He persisted in saying that the nail was in the cavity of the chest, and we were very uneasy until it was found among his bed-clothing, where he had hidden it. We put a special watch on him night and day, the wound healed up, he improved, and the suicidal impulse left him en-

*Read before the Academy of Medicine, Columbus, Ohio.

tirely. Unfortunately, however, he relapsed into dementia, developed tuberculosis, and died. We could not get an autopsy on the case.

At the Columbus State Hospital we have not had a suicide for nearly three years. The plan followed now is to have them all in one ward, a night watch is kept on duty, and in aggravated cases, such as the one I have mentioned, we put on a special attendant, who is not allowed to leave them alone at any time night or day.

When melancholia relapses into the chronic form, the chances of recovery are very small, especially if the patient has been affected over two years. The symptoms of depression continue, they will pick at their clothing, sometimes at their hands and face, until the skin becomes eroded and sores form.

They may also pull out their hair and beard. The face presents a blank expression, and it is difficult to get them to talk, often impossible. These cases usually gradually pass into the condition of dementia. Of the pathology of melancholia but little is known, notwithstanding the fact that we have more deaths occurring in this form of mental disease than any other. Berkley says: "It seems to be a disease of inanition. The only possible explanation lies in a constitutional instability of the nervous system, which may be inherited, or the seeds may have been acquired in early childhood. In the chronic cases, says this same author, coming to the autopsy table there are evidences of old anemias, venous congestion of a passive form, edema of the pia, and of the brain substance, and even general atrophy of the convolutions."

In all cases of melancholia acute, you have indigestion, constipation and coated tongue, offensive breath, and an irritable stomach, evidence of a profound disturbance of the digestive tract; the patient seems to have a perfect distaste for all kinds of food; if they take anything on their stomach they will immediately eject it. The vomited matter is very offensive, in many cases presents the appearance of undigested food that has laid on the stomach for some time without being assimilated. This condition may exist throughout the entire alimentary canal. In these cases lavage of the stomach is often of great value. At the State Hospital recently we have made this a uniform practice, where these conditions exist, and have found it of great value. It is astonishing how rapidly some cases will improve under this method of treatment. It can be done either with a stomach tube, or by a nasal tube. In many cases we find where the stomach is very irritable, they seem to do better when the nasal tube is used; it appears to excite less nausea. If your patient resists, as they most all will, in this class of cases, the nasal tube is the only thing. We usually take water warmed to about 100 degrees Fahr., or thereabout, and add a small quantity of boric acid. After inserting the nasal tube, we pour through a funnel about a pint; or a pint and a half of the fluid; by bending the tube and making a syphon of it, you can usually empty the stomach. If the contents are tenacious, by attaching a Davidson syringe you can draw out the contents of the stomach; this can be repeated several times, depending upon the strength of the patient until the water runs clearer.

The quantity poured into the stomach, and what is removed, should be measured, so that you can tell if you are getting it all away, and not leaving a quantity of medicated solution which might act as an irritant. This should be kept up every day until the patient is able to retain nourishment. The washing out of the stomach in these patients produces such relief that after the first time or two the patient, unless very insane, makes but little resistance. When they become accustomed to it and do not resist, the tube can be placed back over the tongue and so introduced. After the stomach is washed out you can then introduce nourishment in the same manner, beginning usually with a little broth or eggnog, and gradually giving more until you can introduce a considerable quantity every day. As a rule, the patient begins to eat voluntarily. Where emaciation and exhaustion have previously existed, milk, eggnog, any of the predigested foods, soups, etc., should be given as often as possible.

It has been said that moral suasion does little good in these cases, and that there is no use in trying to argue a person so affected out of their delusions. This may be true to a certain extent, but when we are aware that in the majority of cases a person who has improved or recovered from acute melancholia can remember everything that occurred while they were at their worst, it seems reasonable to suppose that they remember your advice, and that it may have done them good. It is of advantage to divert their minds as much as possible from their troubles, and when they are in a condition to do so, we urge them to attend our entertainments and have them taken out in the fresh air as much as possible.

In the way of medication it is almost always necessary to give something to produce sleep, for as a rule they suffer from insomnia.

The hydrobromate of hyoscyne hypodermically is a valuable drug in the badly disturbed cases. A tooth of a grain will often be sufficient to produce a good night's rest. Trional and sulphonal answer the purpose often, and if necessary can be given by the tube while you are feeding the patient, and they refuse to take medicine, as they often do.

Chloral and conium may be used, but are more irritating to the stomach. Calomel in small doses gives satisfactory results in many cases, as it quiets the irritability of the stomach as well as aiding to restore the digestive tract to its normal tone. The bitter tonics, iron, quinine and strychnia, also cod liver oil combined with Parrish food, will be found valuable in many cases. If the patient is weak and exhausted they should be put to bed, and the treatment otherwise can be carried out just the same. The prognosis in acute melancholia is good at least 60% recovering. There is no doubt but what many cases of melancholia can be treated at their homes, where a suicidal tendency is not a marked feature.

When a patient begins to develop delusions of persecution, and evidences a tendency towards suicide, it is dangerous for them to be kept where they have access to weapons of any kind. In the majority of cases a hospital or sanatorium

is the safest place to treat such cases, a change of surroundings will often accomplish a great deal of good by its influence alone.

THE TREATMENT OF ACUTE OTITIS MEDIA.

By FREDERICK L. JACK, M. D.,

of Boston, Mass.

The title of this paper was given me by our Secretary, not I fear with any idea that I should add to the knowledge of one of the most important of ear diseases, but rather to provoke discussion of its treatment. It is important not only because it affects hearing, but because it affects life. To detail before this society the dangers of its extension to vital parts is quite unnecessary.

A personal experience in the line of treatment must necessarily enter into my very brief consideration of the subject. For the sake of emphasizing a few important points in the treatment of this trouble, we may refer to two of its stages. The first one in which there is an hemorrhagic or congestive condition with slight if any bulging of the drum membrane. The second in which there is a secretion of fluid collection in the middle ear with bulging of the drum membrane. As, however, one stage may quickly merge into the other a sharp differentiation apparently cannot be made. To instance a few pathological conditions, there is usually an inflammation and obstruction of the Eustachian tube. In the first stage the injection of blood vessels is often confined to the membrane of Schrapnell and superior posterior quadrant of the drum membrane. In the second stage the bulging of the drum is often confined to the posterior half. Pain is the symptom most complained of by the patient and the one for which he seeks relief.

In the treatment of the first stage we seek to keep open the Eustachian tube. With this object in view in addition to treatment postnasal we resort in children to gentle inflation by means of the Politzer bag, in adults by means of the Eustachian catheter. I believe in early inflation gently performed, without pain to the patient, for by using too much energy we increase rather than diminish the amount of inflammation. Inflation by catheter when practicable seems best, as there can be no danger of exciting trouble in the other ear. It is useless to enumerate the many remedies employed in the region of the fossa of Rosenmüller with the object of diminishing the swelling. Glycerine for its dehydrating properties, and of the more recent ones, adrenalin, seem most efficacious. Heat is often useful for pain. Shall it be dry or moist? In my opinion, always dry. Poultices cannot be too strongly condemned. Consider for a moment the small opportunity for swelling in the ear tract walled in as it is by bone, and that very thin bone separating many important structures. We are all familiar with the boggy condition not only of the ear itself, but also of the surrounding tissues resulting from the use of poultices, which defeats it seems to me what should be our object, i. e., to reduce the amount of swelling. Instillations of warm ear drops for the relief of pain are sometimes useful, but soon produce a macerated condition of the tissues, thereby rendering difficult a proper inspection of the drum.

Oily mixtures for example, olive oil or a preparation of oil and chloroform, are the least objectionable. I consider them, however, no more useful than the external application of dry heat. Of the various anodynes or narcotics for the relief of pain, some form of opium has proved most useful. Milder remedies failing to control the pain, the continued use of potash during the inflammation (in small doses) of bromide or soda on account of its inhibitory action is indicated. In repeated attacks of inflammation in the ear, I naturally believe in eliminating all possible causes, such as adenoids, nasal or post-nasal obstructions.

Second Stage.—A collection of fluid in the middle ear with a bulging drum membrane. Such a condition, in my experience, rarely finds relief from pain or undergoes resolution without a perforation of the drum. A free incision of the drum is of the greatest importance. It is to the practicability of the operation under these conditions that I would call special attention. In speaking of the indications for an incision of the drum membrane, I cannot improve on what I have already stated in a paper read before the meeting of the Massachusetts Medical Society in 1897. "By the operation several desirable ends are at once attained. In the first place, the loss of blood, together with the evacuation of collected fluid, relieves the pressure, and thereby lessens, if not stops, the pain. The rapid healing of cut surfaces, as compared to that of the ragged tear generally produced by spontaneous rupture, has a decided bearing upon the subsequent improvement of the hearing. I believe, also, that an early incision prevents the chances of mastoid or cerebral complications. Ear trouble in very young children is frequently overlooked at least by the general practitioner, a chance observation of aural discharge first attracting the attention. Children usually offer little in the way of objective symptoms; they seldom place the hand over the affected ear, or in any way direct attention to the seat of trouble, whereas the general reflex nervous disorders, caused by the auditory disturbance, cover a wide range of symptoms, from slight twitching to a condition practically of opisthotonos, and to marked retraction of the legs, like that seen in acute abdominal affections." Although it is unnecessary at this time to dwell upon it, I can never allow an opportunity to escape of emphasizing the importance of carefully inspecting the ear in doubtful cases.

There is still another condition in which the opening in the drum membrane is of great service, not only in preventing a possible relapse, but also in restoring hearing. Its importance is less frequently recognized than that which we have just considered. I refer to the collection of fluid, either serous or mucous, in the tympanic cavity, usually following an acute catarrhal inflammation without bulging of the drum membrane as seen in the first stages. The drum membrane, upon inspection, is found depressed from closure of the Eustachian tube, but there is seldom any considerable injection of blood vessels. The color of the drum varies with the relative thickness of the membrane and the nature of the fluid, serous exudation producing a strange color, mucous a dark gray. Often the level of the

fluid is indicated by a dark line. In many cases it is impossible to see the fluid on account of pathological changes in the membrane tympani previous to the attack. We then rely somewhat on the history and upon hearing tests by means of the autoscope after inflation of the middle ear.

I am fully aware that many of these cases improve under other treatment, but I am equally certain that many cases of progressive catarrhal deafness are made permanently worse by neglecting to free the middle ear of its fluid contents. I make this statement advisedly, and with considerable experience in the treatment of these cases, both in the usual way, and by incision through the drum membrane. I have yet to meet a case in which complete evacuation of the fluid through an opening in the drum proved other than satisfactory. On the contrary, it is not an uncommon experience for cases with doubtful history of fluid in the middle ear to present themselves for treatment after the usual means have been employed, with membrane collapsed held more or less firmly in place by adhesive bands. The operation is not difficult, provided the field is properly illuminated; it is only slightly uncomfortable, and the opening usually heals in twenty-four hours.

The auditory canal and drum are first rendered aseptic by instillations of a one to five thousand corrosive sublimate solution. The point of election is in the posterior lower quadrant. A very small incision is very quickly made by a quick thrust with a sharp triangular knife, the fluid being forced out by inflation. The ease and rapidity of evacuation depend upon the nature of the fluid, thick mucous often requiring the use of small forceps, after presenting at the opening; serous fluid, on the other hand, escapes into the auditory canal, and is removed by means of absorbent cotton. Several inflations of the middle ear, by means of the catheter or Politzer bag, are usually necessary to completely evacuate the middle ear. A small plug of cotton is placed in the meatus for twenty-four hours, then removed, and subsequent treatment is directed to the naso-pharynx and Eustachian tube. The relief afforded by paracentesis is immediate, and, with appropriate treatment, the danger of refilling slight. Early paracentesis, under the two conditions I have indicated, will often avert alarming symptoms, and prevent serious results not only as regards the hearing, but even the life of the patient.

By early incision in the second stage less chance is offered for a nipple formation of the drum, an early indication that the healing may be delayed or that serious complications may arise. However, as the condition may be considered subacute, it hardly comes within the scope of this paper.

The point of election for opening is naturally over the portion of the greatest bulging. It is quite unnecessary at this time to describe the technique of operating. Suffice it to say that the incision should be as free as possible to secure good drainage. In adults an anesthetic may be used if so desired, primary anesthesia with ether is preferable, although nitrous oxide or chloroform can be used. It is my feeling that children suffer more from the use of an anesthetic than from a quick operation like an incision of the drum. It is my custom to proceed

without its use. Personally, I have little faith in the anesthetic properties of local application of cocaine on the inflamed ear, nor have I found any drug satisfactory in lessening the pain of an incision. I consider the treatment after the operation important. The use of dry wicks tends, in my experience, to shorten the subsequent course of the inflammation. Syringing is employed after several days, but only in cases in which the secretion becomes thickened and interferes with a free discharge. Many antiseptic fluids are used, although water made sterile by boiling is often sufficient.

Inflations of the middle ear, at intervals, are necessary to evacuate thoroughly the middle ear and should be continued until the healing is restored. It is with a feeling of some embarrassment that I have presented this brief communication upon a well-known subject before experts. The importance of the subject, however, cannot be ever estimated and is one well worthy our thoughtful consideration.

THE CLOSE RELATIONSHIP EXISTING BETWEEN EPILEPSY AND DYSPEPSIA.*

By CHARLES D. AARON, M. D.,

of Detroit.

Professor of Clinical Gastro-enterology in the Detroit College of Medicine, Consulting Gastro-enterologist to Harper Hospital, etc.

Epilepsy is characterized by periodic loss of consciousness accompanied with more or less pronounced general convulsions which run a typical course. It is either a simple symptom of various grave diseases of the brain or a functional neurosis with no traceable anatomical changes in the brain.

Patients may be perfectly well during the interval between the attacks. We have not found a completely satisfactory explanation why the convulsions, loss of consciousness and the complete cessation of reflex action occur simultaneously. We are compelled to assume that there are functional disturbances in the central nervous system, which arise from time to time, and disappear quickly, and that these disturbances are the cause of the epilepsy. We can not doubt that the central nervous system is thus affected, for a proof of this fact lies in the loss of consciousness and in the convulsions.

The phenomena of epilepsy in pronounced cases are so frequent and obvious that the diagnosis presents no difficulty. It is often difficult, however, to differentiate the symptomatic from the idiopathic. Epilepsy is introduced in most cases by an aura, with nervous phenomena which immediately precede the real attack as a prodroma and are designated respectively according to the region through which they have their course. These attacks in a given case usually recur in the same way. The aura may be absent in a very large number of patients, that is, the attack comes suddenly in the midst of complete health.

We must not forget that epilepsy is a complex of symptoms which form an independent disease. In every case, even when the epileptic paroxysm is clearly manifest, we must ascertain whether or not a symptomatic epilepsy may be assumed, especially

*Read before the Michigan State Medical Society at Battle Creek, Mich., May 15th and 16th, 1901.

must we determine whether or not we have an affection of the cortical substance of the brain, such as tumor, etc. Important in the diagnosis of real epilepsy are the irritations which precede the attack and produce the convulsions reflexly. We may have epileptic convulsions after continued irritation of peripheral nerves through cicatrices, foreign bodies, tumors, inflammatory exudates, intestinal worms, diseases of the sexual organs, etc. There is an intimate relation of epilepsy to lesions and irritations of the peripheral nervous system, for we have clinical experience to the effect that the epilepsy disappears completely after the irritation of these nerves has been removed by means of excision. In other cases the connection between epilepsy and an injury due to poisons is less clear. We know that epilepsy attends constitutional and infectious diseases, intoxications, and especially chronic lead poisoning.

The influence which dyspepsia exerts with regard to attacks of epilepsy has been studied for a long time. Galen (1) took care of a young Grammarian whose mental work predisposed him to such crises. He advised good digestive regimen and made this the basis for the treatment. He prohibited for an epileptic infant aliments which produce flatulence and such foods as carry the blood to the head. He forbade wines and other alcoholic drinks and recommended a milk diet. In the study of idiopathic epilepsy we cannot help but notice that there obtains a certain relationship between it and dyspepsia. In some of these cases we see a coated tongue, dilated stomach, abnormal fermentation, fetid stools, and find indican in the urine. In a report by Herter and Smith (2) of thirty-one cases of idiopathic epilepsy they observed a certain relationship between epilepsy and the putrefactive processes in the intestine. They concluded that epileptic paroxysms in many cases were due to the toxic substances in the blood. The degree of putrefaction in the intestine was based upon the analysis of the urine and the amount of indican present. They were able to control some cases of epilepsy by controlling the products of putrefaction in the intestine. I myself have examined the stomach of a few epileptics and in the majority of instances have found it normal.

Eclampsia is due to the retention of the products of metabolism and the convulsions this produces are of various kinds. Reasoning from analogy we may assume that the absorption of toxic material from the stomach and intestine may act upon the cerebral cortex directly or reflexly and thus cause the spasm. Then, again, the substances which irritate the gastric mucosa, in cases where the secretion of hydrochloric acid is excessive or acids of fermentation are present, may act upon the cerebral cortex in a reflex manner and cause the spasm. I do not mean to say that true epilepsy is always connected with digestive troubles, but I hold that there is a class of patients whose epilepsy seems to be directly traceable to gastro-intestinal irritation. When these patients are about to have an attack, the digestive difficulty seems to precipitate the crisis. Then, again, when the digestion is corrected, the crisis seems often to abate.

The following case will illustrate the above. On May 30th, 1899, Mr. N., age 21, consulted me for convulsions with loss of consciousness and indigestion. He gave a history of pneumonia at three years of age and scarlet fever at ten. In the last three years he has had some trouble with his head. He says he feels as though he were going into another world and then there is a loss of consciousness. He could feel a creeping sensation in the head and dimness of vision for an hour previous to the attack. After these attacks he would vomit and belch large quantities of gas. He was examined by Dr. Spratling, medical superintendent of the "Craig Colony for Epileptics," and he declared stomach trouble as the cause, and the case, accordingly, was placed into my hands. The patient suffered somewhat with headache. His attacks were accompanied by an irritation in the stomach. He had such attacks every month at first, but of late they came every eight to eleven days, and they were becoming more and more frequent. The patient did not have the appearance of a dyspeptic, and he ate and slept well. His bowels were regular and the tongue was clean. His stomach contents showed a condition of hyperchlorhydria. The urine contained indican only at times. The patient was put on anti-fermentative remedies as benzosol and resorcin. Atropine was given for the hyperchlorhydria. There was an immediate improvement. After taking the remedies his first attack came only after three months, the next took place in seven months. His diet was small in amount but frequent. Up to four weeks ago he has had three attacks within seventeen months. The crisis are diminishing in frequency and a cure seems to have been achieved. For the past four weeks the attacks have reproduced themselves with less frequency and with less intensity.

In infants, stomach trouble frequently produces convulsions which resemble epilepsy. These cases usually respond quickly to rational treatment. March 15, 1898, I was called by Dr. Delos Parker, of Detroit, to see Master H., age two and a half years. The history brought out the fact that the patient had spasms nearly every night since birth. There was mucus in his feces, eructations, and all symptoms of gastro-intestinal fermentation. The patient was placed upon benzosol and resorcin and the attacks decreased. He has improved in health and has made a complete recovery, for he has not had a spasm in three years.

Digestive troubles are frequently latent and it is to be recommended in all cases of epilepsy and suspected stomach disorder that an analysis of the stomach contents and urine be made. To determine the condition of the patient this should always be done, even if there be a want of subjective symptoms. The examination of the patient is not complete unless the digestive organs are also examined. This examination is of the greatest importance here, because success depends upon making the diagnosis as comprehensive as possible.

Changes in the Medical Corps of the Navy, Week Ended
September 28, 1901.

ASSISTANT SURGEON F. A. ASSERSON, ASSISTANT SURGEON J. W. BACKUS, ordered to the Naval Hospital, Cavite, P. I.—Sept. 20.
ASSISTANT SURGEON A. E. PECK, ordered to Manila, Sept. 20.
ASSISTANT SURGEON C. R. BURR, resignation accepted to take effect Sept. 25—Sept. 24.
ASSISTANT SURGEON D. G. HEHE, detached from the Marietta, and ordered home to wait orders, when vessel is put out of commission.—Sept. 24.
ASSISTANT SURGEON E. J. CROW, detached from the Castine, when put out of commission, and ordered home to wait orders—Sept. 24.
PASSED ASSISTANT SURGEON E. M. SHIPP, detached from the Naval Hospital, Cavite, and ordered to the Celtic.—Sept. 26.
ASSISTANT SURGEON W. L. BELL, detached from the Celtic and ordered to the naval hospital, Cavite, P. I.—Sept. 26.
ASSISTANT SURGEON J. W. BACKUS, detached from the Naval Hospital, Cavite, and ordered to the Brooklyn.—Sept. 26.
ASSISTANT SURGEON F. A. ASSERSON, detached from the Naval Hospital, Cavite, and ordered to the General Alayut, Sept. 26.

Official List of the Changes of Station and Duties of
Commissioned and Non-Commissioned Officers of the U. S.
Marine Hospital Service for the 7 days ended September 12,
1901.

J. O. CORB, passed assistant surgeon, granted 5 days extension of leave of absence from September 13, 1901.
RUPERT BLUE, passed assistant surgeon, granted 5 days extension of leave of absence—September 6, 1901.
J. A. NYDEGGAR, passed assistant surgeon, relieved from duty at Cape Charles Quarantine and directed to proceed to Cairo, Ill., and assume temporary command of service during absence of Passed Assistant Surgeon J. H. Oakley, on leave—September 12, 1901.
Granted 2 days leave of absence from September 10, 1901—September 9, 1901.
J. F. ANDERSON, assistant surgeon, directed to report to medical officer in command, Immigration Service, New York, N. Y., for duty—September 9, 1901.
C. W. WILHE, assistant surgeon, directed to assume command of service at Cape Charles Quarantine, relieving Passed Assistant Surgeon J. A. Nydegger—September 12, 1901.
G. H. ALTREE, acting assistant surgeon, granted leave of absence for 14 days—September 9, 1901.
F. N. BARNESBY, acting assistant surgeon, granted leave of absence for 1 month from September 1, 1901—August 30, 1901.
R. E. EBERSOLE, acting assistant surgeon, granted 3 days' extension of leave of absence from September 9, 1901—September 7, 1901.

Official List of the Changes of Station and Duties of
Commissioned and Non-Commissioned Officers of the U. S.
Marine Hospital Service for the 7 days ended September 19,
1901.

EUGENE WADDIN, surgeon, relieved temporarily from command of the service at Buffalo, N. Y., and assigned to special duty with the President—September 13, 1901.
Detailed to represent the service at meeting of the American Public Health Association, September 16-20—September 13, 1901.
W. J. PLETTS, surgeon, granted leave of absence for 2 months from September 15—September 14, 1901.
R. M. WOODWARD, surgeon, detailed to represent the service at meeting of the American Public Health Association, September 16-20—September 13, 1901.
M. J. ROSENAU, passed assistant surgeon, detailed to represent service at meeting of the American Public Health Association, September 16-20—September 13, 1901.
Granted leave of absence for 1 day, September 14—September 15, 1901.
DINLOP MOORE, assistant surgeon, relieved from duty at Nome, Alaska, and directed to proceed to the States and await orders—September 13, 1901.
G. H. ALTREE, acting assistant surgeon, granted leave of absence for 14 days from September 9—September 14, 1901.
J. G. STANTON, acting assistant surgeon, granted leave of absence for 18 days from September 13—September 14, 1901.
W. O. WETMORE, acting assistant surgeon, directed to assume temporary command of service at Buffalo, N. Y., during absence of Surgeon Eugene Waddin on special detail—September 13, 1901.
J. W. STEVENSON, acting assistant surgeon, granted leave of absence for 16 days from September 9, 1901—September 11, 1901.
W. S. WALKLEY, acting assistant surgeon, granted 3 days leave of absence, from September 12, 1901—September 10, 1901.
JUAN R. XIQUES, acting assistant surgeon, granted leave of absence for 30 days from September 1, 1901—September 12, 1901.
J. Y. PORTER, sanitary inspector, directed to visit Key West, Miami, Jacksonville, Fernandina and Mayport as appraiser—September 6, 1901.
I. W. RYDEK, hospital steward, directed to report to Director of Hygienic Laboratory for temporary duty—September 11, 1901.

Official List of the Changes of Station and Duties of
Commissioned and Non-Commissioned Officers of the U. S.
Marine Hospital Service for the 7 days ended September 26,
1901.

S. D. BROOKS, surgeon, granted leave of absence for 11 days from September 23—September 24, 1901.
H. S. CUMMING, passed assistant surgeon, granted leave of absence for thirty days, on account of sickness—September 26, 1901.
S. B. GRUBBS, assistant surgeon, granted leave of absence for 11 days from September 25—September 20, 1901.
H. B. PARKER, assistant surgeon, to proceed to Jacksonville, Fla., for special temporary duty—September 23, 1901.
W. C. HOBDY, assistant surgeon, to proceed to South Atlantic Quarantine as inspector—September 21, 1901.
P. J. THORNBURY, assistant surgeon, relieved from duty at Dutch Harbor, Alaska, and directed to return to the States—September 20, 1901.
L. P. GIBSON, acting assistant surgeon, granted leave of absence for 10 days on account of sickness—September 17, 1901.
E. B. HALLETT, acting assistant surgeon, granted leave of absence for 3 days from September 24—September 23, 1901.
A. B. McDOWELL, acting assistant surgeon, granted leave of absence for 20 days from October 12—September 21, 1901.
HENRY OWEN, acting assistant surgeon, granted leave of absence for 10 days from September 24—September 16, 1901.
S. D. ROBBINS, acting assistant surgeon, granted leave of absence for 30 days from September 6, on account of sickness—September 20, 1901.
M. R. MASON, hospital steward, relieved from duty at Dutch Harbor, Alaska, and directed to return to the States—September 20, 1901.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended September 28, 1901.

Some Timely Papers.—We publish this week a series of short papers illustrating some phases of the surgery of the stomach. In view of the lamentable case of President McKinley these papers are especially timely and instructive. The case reported by Dr. Roberts had some striking resemblances to that of the President; and it illustrates the fact that the policy of non-intervention can be quite as fatal as operation. And yet, let us suppose for a moment that the President had been treated on this expectant plan. What an outcry there would have been from the over-zealous and too eager critics!

The case reported by Dr. Penn is of especial value because it appears without a doubt to have been one of pistol-shot wound of the stomach followed by recovery. Of course, as there was neither operation nor autopsy, it is impossible to state exactly what the surgical lesions were, but the clinical evidence of a wound of the stomach is quite conclusive. This case gives an embarrassing reply to the pessimists who have been claiming that recovery in cases like that of President McKinley is impossible.

Dr. Hammond's paper illustrates what surgery can accomplish in an elective operation on the stomach. If the viscus tolerates such manipulations, why not also in the case of some gun-shot wounds? We know, in fact, that it does.

Dr. Fischer's paper, which is entirely clinical and pathological, relates a case of tubercular ulcer of the stomach.

Traumatic Surgery of the Upper Abdomen.—The case of gunshot perforation of the kidney, with incidental non-perforating wound of the stomach, reported by Dr. Roberts in this issue of **The Philadelphia Medical Journal**, emphasizes the difficulty of diagnosis and treatment in traumatism of the upper regions of the abdomen. The patient had a wounded kidney, from which the blood slowly flowed, and death followed in thirty odd hours from hemorrhage and sepsis combined. Yet there was no discoloration of the urine from blood, no tympanitic distension of the abdomen, and no evidence

at bedtime on the day of injury that the patient was in a dangerous condition. The woman was carefully watched, by nurses, resident surgeon and attending physician, for symptoms pointing to the need of exploratory celiotomy, and yet no symptoms were recognized that seemed to demand such a step, until too late. Death occurred, and the autopsy showed that immediate operation might have saved life by stopping the renal hemorrhage and averting the dangers of sepsis.

The injury was much like that of the late President McKinley, except that the gunshot wound in the latter instance did more damage to the stomach and less to the kidney and also involved the pancreas. The surgeons, who attended the President, promptly and wisely opened the abdomen and sutured the gastric perforations. Yet death occurred as in the case of Dr. Roberts, who refrained from operation. In both instances there was clinical evidence before death of septic contamination of the wound. It is probable that the President's death was due to septic gangrene due to the missile, and that death in the case reported to-day was partly due to septic contamination from the bullet.

Cases of this character illustrate the great responsibility of the surgeon in dealing with penetrating wounds of the belly above the navel. Such lesions are known to be less likely to cause intestinal perforation, with consequent extravasation of feces and fatal septic peritonitis, than injuries lower down. Hence it might be inferred that they are less dangerous than wounds below the navel. This deduction is probably incorrect. Though intestinal perforation is less probable, injury to stomach, pancreas, gall bladder, kidney and larger vessels is very common. Some of these lesions do not seem to lead so promptly to septic peritonitis as bowel wounds, but their fatality points to the need of prompt exploratory abdominal section.

The recent experience of military surgeons, in the Spanish-American and the South African wars, has seemed to suggest a reconsideration of previous opinions on this subject. It is probably true that, during the exigencies of a campaign, wounds of the abdomen, due to jacketed bullets of small

calibre, will have less mortality, if treated on the expectant rather than the operative plan. Such injuries occurring in civil life, where aseptic surroundings, accurate hospital nursing and skilful operators can be assured, will doubtless do better, if prompt recourse is had to abdominal section for direct treatment of the internal lesions.

A recent case in the writer's hands seems to confirm the wisdom of this course. A young man received an antero-posterior gunshot wound in the lumbar region. The ball was found under the skin on the anterior side of the body. The patient showed no shock and so little evidence of injury that it was supposed that the bullet had been deflected and traveled between the muscular planes of the trunk. The attending physician was so convinced that no internal lesion had occurred that he put the patient on ordinary diet, though he kept him in bed for observation. Repeated examination of the abdomen by the surgeon, accompanied by a careful register of the pulse rate, respirations and temperature, served only to confirm the diagnosis of no intra-abdominal damage. The patient was, however, given no food by the mouth and treated tentatively as a possible case of perforation of the intestines; largely because of the size of the bullet and the manner of the shooting. In a few days the man suddenly became worse and died. Autopsy showed several intestinal wounds.

This case indicates the impossibility of treating abdominal wounds with safety when the surgeon is in the dark as to the nature of the damage done to the viscera. Under modern methods aseptic exploratory incision is practically free from danger. A knowledge of the condition within the abdomen is more necessary to efficient treatment than celiotomy is dangerous. Civil surgeons will therefore probably continue to adopt exploratory incision in stabs and gunshot wounds of both the upper and lower regions of the abdomen, despite the recent experience of military surgeons.

Many valuable contributions have recently been made to the literature of the surgery of the upper abdomen. The Transactions of the American Surgical Association for 1900 and 1901 are especially rich in papers dealing with this region. The trend of opinion seems to be toward an extension rather than a restriction of operative diagnosis and treatment. Readers of *The Philadelphia Medical Journal* interested in this department of surgical practice will find much material for thought in Maylard's "Surgery of the Alimentary Canal," Frazier's article on the "Surgery of the Stomach" in the *American Journal of the Medical Sciences* for May, 1900, and Keen's "Cartwright Lectures on the Sur-

gery of the Stomach" in the *Philadelphia Medical Journal* for May and June, 1898.

The Emergency Hospital at the Buffalo Exposition.—Physicians who have visited the Pan-American Exposition must have been interested in the Emergency Hospital. We recently had an opportunity to inspect this now historic building, and were much impressed with its excellent arrangement and equipment. It is under the direct care of Dr. Roswell Park, who has for his assistants Dr. A. F. Zittel, Dr. G. McK. Hall and Dr. E. C. Mann. There are twenty-four beds, and five thousand cases have been treated since the opening. The great majority of these cases have been of minor surgery and slight medical ailments. But few operative cases have occurred, the most serious one having been that of President McKinley. Considering the size and character of the Exposition this immunity from grave cases is quite remarkable, and speaks well for the general management and hygiene of the big show. The Hospital is free to all; no charge is made to any one, visitors and attendants at the Exposition having all alike the privileges of the institution. The expenses are borne by the management of the Exposition. Many of the instruments and appurtenances are exhibits—a very practical way of showing their efficacy. The operating room is small, but well lighted and well equipped. It was in this room that the operation on the President was performed. Six nurses are in attendance.

The architecture and general appearance of the building are pleasing. The place is always open for inspection and is in perfect order. This little hospital is not only a useful object lesson, but in its brief existence it has played a most important rôle in the public eye. The managers of the fair are to be commended for providing such a model little infirmary.

A Yellow Fever Institute.—It has been a happy thought to establish an institute for the special study of yellow fever. We publish elsewhere Dr. Wyman's letter and announcement. It would be a good thing if each of the principal diseases besides yellow fever—such as tuberculosis, typhoid fever, malaria, and perhaps syphilis and leprosy—were to be taken under the special care of the Government in some such an institute. The test will probably be made in the case of yellow fever; if this proves successful, separate institutes will be established for the other diseases. We know that whatever the general Government does in such matters is usually well done—in marked contrast to what is sometimes seen in the various States and cities. By the proposed method the medical officers of the Marine Hospital Service will be stimulated to exert them-

selves outside of the routine hospital work, and the activity of others, not connected with the service, can also be utilized. We should suppose that membership in this institute could be by invitation. Doubtless prominent physicians would be glad to avail themselves of such invitations, and undeserving and undesirable members could be excluded by the exercise of a little care.

The field covered by the Marine Hospital Service is very extensive; in fact, it extends almost over the world. Medical officers in Central and South America, and all consular officers, could thus be not only invited but urged to work. The scheme is a most satisfactory one, and we shall look with confidence for valuable results. Whatever the Government says, generally goes.

Man Proposes but the Mayor Disposes.—An earnest effort was made last winter by the Philadelphia County Medical Society and the Pennsylvania Society for the Prevention of Tuberculosis to have pulmonary tuberculosis added to the list of infectious diseases returnable to the Bureau of Health of Philadelphia. The advantages of registration are fully appreciated in New York City and in the States of Maine, New Jersey, Michigan and Washington, where laws have been enacted and where the health boards cooperate earnestly with physicians in endeavoring to limit the spread of tuberculosis. If every case of tuberculosis were registered, the Bureau of Health would watch houses which are occupied by consumptives and require their disinfection when vacated. The medical profession and the public would welcome the protection which judicious measures would afford. The Bureau of Health of Philadelphia adopted a resolution in March which was pronounced to be within its province by a legal opinion from the City Solicitor, providing for registration; it met with the approval of the Director of Public Safety—and there it stopped. His Honor, the Mayor, said "Thus far shalt thou go and no farther," and placed his objection on the ground that there are not sufficient funds at this time available to allow the Bureau of Health to extend their work beyond their present labors. He is the arbiter of matters of hygiene in the municipality.

Almost all large cities in the New England States and in New York and the better regulated Western cities have ordinances providing a penalty for spitting in street cars, in public places and on the sidewalks. In New York City and Boston the penalty is not over \$100. A resolution of a moderate nature was framed and presented to the Common Council, providing for a penalty of \$10 for the

first offence and \$50 for each subsequent offence. The Bureau of Health knew the value of such a law and would have welcomed it—but the Mayor heard of it and it was tossed aside. Paul may plant and Apollos water, but one unsympathetic executive who does not understand preventive municipal and personal hygiene, may be fairly charged with the failure to bring Philadelphia, in this respect, in line with the best regulated cities in the country. The tubercle bacillus seems to be a privileged character. He can hold his head erect and walk up and down our streets, ride free on our street cars, and settle himself comfortably in our offices and private apartments; he seems to have police protection and no one can say him nay. The only place where he has any difficulty in effecting an entrance is in some of our well known hospitals. But he is really the worst anarchist that ever came to our shores, and instead of electrocuting him we give him a front seat on our mortality report every week.

The New Psychology.—Professor G. Stanley Hall, of Clark University, attributes the birth of the "New Psychology" to the work of E. H. Weber on sensation. The "New Psychology" seems to us to have had so many births that one birth more or less does not seriously matter. Weber, it will be recalled, tested the sense-perception by noting at what distances two pin points could be distinguished on the various surfaces of the body. The New Psychologists have always claimed that this work was "epoch-making," but this praise seems to us to be rather extravagant. There is a deal more in psychology than can ever be measured at the point of a pin. The great weakness of the New Psychologists consists in this very fact, that they think they can measure psychological phenomena with such instruments of precision as are used in the physiological laboratory. To point out the rate of speed of a sensation; or the time reaction of a voluntary motion; or the rapidity of a thought; or the power of perception to distinguish two pin points at a certain distance—all this slight-of-hand, and much more like it, will never solve the real problems of psychology. Such phenomena are but superficial and mostly irrelevant manifestations of the "psyche" within. It does seem sometimes that medical men and other physical scientists take a very inadequate view of the functions of nerve-matter. We do not intend to disparage physiology or any of its methods, but we sometimes wonder whether in our quest for the new psychology we have not swung too far away from the old psychology with its introspective method of study by means of self-consciousness.

Variations in the Activity of the Tubercle Bacilli.

—In view of the interest in the subject of tuberculosis excited by the recent Congress in London, the results of some experiments performed by Lartigau (*Journal of Medical Research*, July, 1901) are of considerable interest. Starting out with the idea that possibly bacilli derived from different sources might vary considerably in virulence, he obtained cultures from various lesions in human beings, such as tuberculous lymph glands, pulmonary tuberculosis, and bone and joint tuberculosis. He found that the morphological features were fairly uniform. In those organisms in which the virulence was greatest, the growth upon culture media was usually least. In one instance a bacillus was obtained from a human being that produced a culture not unlike that described by Theobald Smith, as characteristic of bovine tubercle bacilli. This bacillus was excessively virulent, and corresponds also in this respect with Smith's description of the bovine bacillus. The inoculation experiments confirm Lartigau's belief that the virulence of the tubercle bacillus varies considerably. Now, supposing that his hypothesis is correct: we have presented to us the interesting fact that the tubercle bacillus may manifest great variability in its virulence, and we should expect as a result, that the clinical manifestations of human tuberculosis would also be very variable. Of course, clinical experience has long taught us that this is true. We might expect, moreover, that types of infectious disease hitherto unrecognized as tuberculosis, might possibly be due to this germ situated in such a position, and producing such lesions, that is has hitherto not been recognized, or at most, only occasionally. This appears to be true also of the chronic recurrent fever of Ebstein-Pel. The field thus opened to clinicians and pathologists is very great.

Up to the present, with the exception of Lartigau's experiments, careful studies of the tubercle bacillus obtained from different cases, or rather different varieties of this infection in human beings, have not been made, and Lartigau characterizes his communication merely as a preliminary report. It would be of the greatest interest, and, we believe, of the greatest importance to human beings, if such studies could be made, and could be made available clinically for the purpose of prognosis. It so frequently happens that patients in the early stages of the disease are sent to favorable climates, and nevertheless die of what appears to be a fulgurant form, while other patients, in whom the lesions are well advanced, are sent to the same climates and recover apparently completely. If, in some way, we could

understand why this occurs, it would be of the greatest value in guiding our treatment.

Malta Fever.—Malta fever is a very curious and interesting disease. In spite of the careful studies of Bruce, and of the School for Tropical Diseases at Netley, the profession at large has scarcely become so familiar with it either by reading or by personal observation that they are on the lookout for cases. Nevertheless, there is reason to believe that the disease will soon exist in the United States; for its existence in the Philippines has been conclusively demonstrated and cases have been reported from Porto Rico; and from both these places patients suffering from the disease have returned to the continent. Curry (*Journal of Medical Research*, July, 1901) has recently reported four cases which he observed in the Army and Navy General Hospital at Hot Springs, Arkansas. The patients were all soldiers or sailors who have served in the Philippine Islands. The diagnosis upon admission was chronic rheumatism. The duration of the disease had been from six to sixteen months. The patients suffered from anemia, sweating and constipation. Typhoid fever, malaria and rheumatism were readily excluded, and the blood of all gave the characteristic serum reaction with the germ. In view of these observations, and of the report of a case of the disease in Philadelphia two years ago, it behooves us to be on our guard in all cases of persistent disease of febrile course, the nature of which is obscure.

The Supraorbital Reflex.—Of the finding of reflexes there is no end. Everywhere that there is a sensory nerve that bears the slightest relation to any motor nerve, it is discovered that irritation of one produces a response in the other. The last, and in some respects, the most interesting of all newer reflexes is that of McCarthy, of Philadelphia (*Neurologisches Centralblatt*, Sept. 1, 1901). This is elicited by striking with a percussion hammer upon the trunk of the supraorbital nerve or one of its branches, which produces a momentary, lightning-like contraction of the orbicularis palpebrum. Exaggeration of the reflex is detected by the fact that percussion upon any portion of the distribution of the nerve causes the twitching; diminution, by the fact that the twitching is slight, and that the blow must be struck exactly upon its trunk. The arc of this reflex apparently consists of the fifth and seventh nerves. The reflex is lost occasionally in locomotor ataxia, and was absent in one case of paralysis of the fifth nerve, without involvement of the seventh upon the same side. McCarthy regards it as important because it is an example of a purely sensory nerve (the supraorbi-

tal) producing motion in a purely motor nerve (the seventh). Clinically, its value has not yet been demonstrated, but we do not doubt that in time it will be found to be of service in various conditions.

Correspondence.

UNUSUAL AFTER EFFECTS OF A SNAKE BITE, THAT MIGHT HAVE BEEN CAUSED BY THE LOCAL USE OF CARBOLIC ACID.

By JOHN GLENDON SHELDON, M. D., of Telluride, Colo., Surgeon in Chief to the Montrose Hospital; Consulting Surgeon of the Telluride Hospital.

To the Editor of the Philadelphia Medical Journal:

Lawrence E. Holmes, in a paper entitled "Unusual effects of a snake bite", published in the *Philadelphia Medical Journal*, September 14th, 1901—reports a case of snake bite that was dressed with carbolic acid and was followed by anesthesia of the affected member. The purpose of my writing is to review the clinical cause of Holmes' case and to suggest that the unusual symptoms might have been due to the use of carbolic acid.

Holmes' patient—a female twenty-one years of age—was bitten, on the ulnar side of the right forearm, two inches above the wrist joint, by a supposedly non-poisonous snake. The wound was incised; after which it was washed and dressed with a 10% solution of carbolic acid. Everything went well till the fifth day; then the patient complained of weakness and of numbness in the right hand. On examination complete anesthesia was found, which extended, posteriorly, to the carpo-metacarpal articulation, anteriorly, as high as the wound. The pain was severe. Two days later, the pain was less marked and the entire extremity below the wound was anesthetic. Movements of the hand were impaired; but the circulation seemed normal. In a few days the symptoms disappeared. No necrosis or gangrene occurred; and no exfoliation of the skin was mentioned.

Dr. Holmes thought the symptoms were due to hysteria, or to toxic neuritis caused by the serpent's venom. The patient was not a neurotic; there were few, if any, general symptoms and the symptoms did not appear till four or five days after the arm was dressed.

The anesthesia, in this case, cannot be reasonably explained unless it is attributed to the carbolic acid; and I am inclined to believe that this drug was responsible for the local changes that the doctor described. I have not read reports of similar cases, but if carbolic acid is capable of producing such grave conditions as sloughing and gangrene—as it sometimes does—I can see no reason why less severe injuries, as in the case reported, might not result from its use. This case—characterized by symptoms which might be explained by nerve involvement with absence of circulatory changes—might be cited to uphold Krotum's theory of carbolic acid gangrene; namely, that the gangrene results from specific action on the nerves.

Multiple Hemorrhages of Hysterical Origin.—At a meeting of the Medical Society of the Paris Hospitals, (*Bulletin et Memoires de la Societe Medicale des Hopitaux de Paris*, 1901, No. 13), Paul Sainton reports the case of a woman of 25, of neurotic ancestry, four months pregnant, who complained of hemorrhages from the mucous membranes. After being very angry, metrorrhagia occurred, lasting four days, without affecting the pregnancy. Following this, auricular, mammary, buccal hemorrhages, and epistaxis appeared. The otorrhagia occurred three times, always from her right ear. From the nipples the hemorrhages were frequent, and have persisted irregularly since. In each case she has some odd feeling before the hemorrhage begins. The mouth shows no ulcers or other possible cause of hemorrhage. Her general condition is excellent. There is some leukocytosis (18,000), probably due to the pregnancy. There is some anesthesia and pain over the ovaries. She is very neurotic. The symmetrical condition and its rarity make the case most interesting. There was no doubt that the hemorrhages were of hysterical origin. [M.O.]

Reviews.

The Ready Reference Hand Book of Diseases of the Skin. By George Thomas Jackson, M. D., (Col.) Chief of Clinic and Instructor in Dermatology, College of Physicians and Surgeons, New York; Consulting Dermatologist to the Presbyterian Hospital, New York, and to the New York Infirmary for Women and Children; Member of the American Dermatological Association, and of the New York Dermatological Society. With 80 illustrations and 3 Plates. Fourth Edition. Thoroughly Revised. Lea Brothers & Company, New York and Philadelphia, 1901.

The fourth edition of this manual, although no bulkier than its predecessor, contains new sections upon the following more recently described dermatoses: Acne keratosa, acne urticata, caraté, craw-craw, endothelioma cutis, erythrodermic pityriasis en plaques disseminées, Fordyce's disease of the lips, granuloma necrotica, lichen annularis, lichen pilaris, pityriasis lichenoides chronica and verruga peruana. The consideration of these affections is succinct yet sufficiently comprehensive to convey an intelligent idea of their nature. The author has kept his book thoroughly up to date, at the same time preventing it from becoming voluminous by careful pruning and condensation of the text. The chapter upon new local remedies is fully abreast of the advances in therapeutics both here and abroad. The liberal space devoted to formulae of prescriptions and recent innovations in treatment will commend itself to practitioners. In view of the general excellence of the work it is perhaps hypercritical to call attention to its few minor omissions and inexactnesses. No mention is made of the use of large doses of quinine in lupus erythematosus, although this will probably be proven to be one of the most useful drugs in this most obstinate affection. Under the pathology of this disease reference is made "to a thrombus brought from some distant part": This is in all probability an inadvertence. The X-ray treatment of hirsuties is described as "apparently successful": this is scarcely justified by recent reports which tend to show that superfluous hair removed by this means is extremely prone to return. The book is a faithful exponent of modern views on dermatology and may be recommended as a safe guide for students and practitioners of medicine. [J. F. S.]

Diseases of the Respiratory Organs, Acute and Chronic. By William Waugh, A. M., M. D. Chicago: G. P. Engelhard & Co., 1901.

In presenting this work, the author remarks in his preface that "the treatment of acute affections of the respiratory organs has progressed far beyond that given in the text books on Practice." With that object in view, he has prepared this work, a book of 201 pages, giving special prominence to treatment. He also states that "the methods of treatment herein advocated are based upon the author's conception of the role played in acute inflammations by the vasomotor nerves, and his belief that the future of scientific therapeutics lies in the study of such pathologic states, and the influence of drugs upon them, rather than in the consideration of these maladies as pathological entities." The book is arranged in two parts: the first is devoted to the consideration of acute respiratory diseases, and the second to chronic respiratory diseases. In discussing the treatment of hemoptysis, he advises quietude for the patient, application of cold to the chest, elevation of the head somewhat, and the administration of atropine, and aconitine or veratrine when the heart action is bounding. He deems a thorough examination of the chest necessary. It is quite generally admitted that an examination of the chest, immediately after a pulmonary hemorrhage, is a dangerous procedure. Opium is not mentioned in the treatment of this condition, yet it undoubtedly is a valuable agent. There are other topics open to criticism, and in conclusion, we desire to emphasize one of the author's prefatory remarks in regard to the vasomotor nerve therapy, which is in accord with our views, namely, "that the subject is but in its formative state, and is by no means presented as a finished product." We do not believe this work will meet with the general approval of the profession of this country.

[F. J. K.]

Kurzgefasstes Lehrbuch der Kinderheilkunde fuer Aerzte und Studierende, von Dr. Carl Seltz, A. O. Universitätsprofessor und Vorstand der Kinderpoliklinik am Reisingerlanum in München. Second Edition, Enlarged and Thoroughly Revised. Berlin, 1901. S. Karger. Pp. viii, 499.)

The author's aim, as stated in the prefaces, has been to present a concise but exhaustive textbook for practitioners as well as for students, touching upon all the topics peculiar to childhood and its diseases, while paying special attention to physiology, hygiene and dietetics. The chapters on the latter subjects have been rewritten and it gives us pleasure to commend especially that on infant feeding. The present edition has been brought up to date by the addition of a number of new chapters among which are to be noted those on scurvy, chondrodystrophy, status lymphaticus, congenital stenosis of the pylorus, etc. Among other well-written parts are those on methods of examination, on tuberculosis and on pneumonia, and in the last-mentioned the statement is very properly made that the croupous form is very common in infancy and childhood. In the diagnosis of meningitis mention is made of the importance of lumbar puncture and its aid when positive results are obtained. In the treatment of intussusception surgical intervention is recommended within 24 or 36 hours. If rectal injections of air or liquid have not effected reduction; the tendency in America is to attempt reduction by these means, and, if not successful, immediate laparotomy. Beyond this and the rather scanty index, with one or two other minor points, it is difficult to find fault with the work, and we heartily commend it to those who can read German and who desire a good text-book on pediatrics as a book well worth buying. [A. H.]

Mt. Sinai Hospital Reports.

Volume II. For 1899 and 1900. Edited for the Medical Board. By Paul F. Mundé, M. D., LL.D. 1901.

The publication of hospital reports made up of studies of cases and disorders under the observation of the attending physicians subserves a useful purpose over and above the inherent value of the work in that it stimulates careful study, so that in this way not alone are the interests of the individual patient safeguarded, but also the literature of medicine is enriched, and the way is paved for the future application of measures of prevention, of palliation, or of cure. The staff of the Mt. Sinai Hospital contains names distinguished in the annals of medicine, and the papers contained in this volume demonstrate the value of good environment, association and example. The more strictly medical side of the hospital work is represented in this volume by 16 interesting essays, while the surgical side is represented by a collective report, in which are detailed many cases of great interest. There are besides reports from the gynecological, the ophthalmological and the otological services, and one or another communication of a miscellaneous character. Mt. Sinai Hospital is already well and favorably known for its work in medicine and surgery and these reports will help to sustain a deserved reputation.

[A. A. E.]

Catherization and Urethral Lavage.—In Catheterizing in stricture of the urethra, Hartmann states that no force should ever be employed. (*L'Independance Medicale*, 1901, No. 21). For it may cause retention, ulceration, cicatricial stricture, abscess, or infiltration of urine. The instrument should be allowed to slide in "by contact," along the urethral wall. Hartmann uses an olive pointed bougie; or, a bundle of thin bougies may be introduced up to the stricture, which one of them may pass. The next day, the same and the next sized bougie may be passed. In some cases, the bougie is left in place a day or two. For urethral injections, Hartmann uses a thin open sound through which the solution is injected as far as he wishes, and is then allowed to run out between the sound and the urethral wall. Upon removing the sound, an injection must be given to wash out the urethral wall from behind forward. But he considers the ordinary injection best, the reservoir being raised 15 m. The solution should be at a temperature of 100° F. As soon as the patient feels like urinating, the injection is stopped. [M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Temple College Medical School.—An announcement has come to us that the Chair of Pathology and Bacteriology and the Chair of Surgery will be open for application until October 17th.

University of Pennsylvania Medical School.—The following appointments have been announced: Dr. M. Howard Fussell has been appointed assistant professor of medicine. Dr. Thomas R. Neilson, assistant professor of genito-urinary diseases, and Dr. Elsha H. Gregory, Jr., demonstrator of anatomy. Dr. Frederick A. Packard will deliver the lectures upon applied therapeutics, and Dr. H. C. Wood, Jr., those on the physiological action of drugs. In the place of Dr. Horatio C. Wood, professor of therapeutics, who has been granted leave of absence for a year. The appointment of clinical professor of nervous diseases has not yet been made. Provost Harrison announced that the commencement exercises will be held in the future upon the third Wednesday in June. As the term is to begin on the last Friday in September, the session will approximate that of Harvard and Yale in length.

College of Physicians, Philadelphia.—Abstract of the monthly report of the Honorary Librarian, Mr. Charles Perry Fisher, June to September, 1901:

Books, pamphlets and journals received:

General Library: 199 volumes, 2053 pamphlets, 7779 journals

Lewis Library: 17 " 0 " 0 "

S. D. Gross Library: 2 " 0 " 0 "

2010 2053 7779

Accessions, 1716 volumes; Duplicates, 264 volumes; Donors, General Library: 85.

Society Meetings Next Week.—The following sections of the College of Physicians and Surgeons of Philadelphia will hold meetings next week, at 8.15 P. M.:

Monday, October 14, Section on Medicine.

Tuesday, October 15, Section on Ophthalmology.

Wednesday, October 16, Section on Otology.

Thursday 17, Section on Gynecology.

Public Health Report for September.—During September, 116 cases of smallpox, 234 cases of diphtheria, 152 cases of scarlet fever, 407 cases of typhoid fever, and 214 cases of consumption were reported, a total of 1033 cases of the contagious diseases for the month. The number of smallpox cases during the month of September was more than half of the total number reported since January 1st.

The Obstetrical Society of Philadelphia held its regular meeting at the College of Physicians and Surgeons Thursday evening, October 3rd. The Society was called to order by the president, Dr. John C. Da Costa. Following the reading of the minutes, which were approved, Dr. Erck reported a case of **fibromyoma of the uterus in a woman of 46**. She had had two children, both labors having been normal. For six years she has had menorrhagia, and lately metrorrhagia, the hemorrhages being profuse. The tumor reached the umbilicus. Hysterectomy was performed, and the tumor exhibited to the Society. Dr. Erck believes that in fibromyoma of the uterus of this size, hysterectomy is advisable; that all smaller benign tumors should be removed, since they may eventually become malignant. In the discussion which followed, Dr. John M. Fisher stated that hysterectomy was necessary in this case, as the tumor was not encapsulated. When it is encapsulated, he advises enucleation. He believes that all fibromyomata of the uterus should not necessarily be removed, since the tumor often remains stationary and causes no trouble. Dr. Hammond believes that if all such tumors were removed many women would be subjected to the operation who are now in excellent health. In Dr. Erck's case, however, the growth could only be dealt with by removal. Dr. Da Costa also considered the removal of the tumor necessary, but does not think it necessary to remove all small fibroid growths. In these cases he advises the use of thyroid extract. In concluding the discussion, Dr. Erck stated that the growth should only be left if the case remains under observation. Dr. Hammond reported the case of a woman who, until ten years ago, enjoyed good health. She then had a miscarriage of three months, since when she has never been entirely well. Six months later pelvic pains developed which confined her to bed for three

months. Upon examination the abdomen was found markedly tympanitic, and so tender that it could hardly be palpated. Her temperature was 103°, pulse 120 and the bowels had not moved for a week. Digital examination showed the uterus pushed forward directly beneath the pubis. The pelvic cavity seemed filled with fluid. Upon opening the abdomen a large amount of pus escaped from the free peritoneal cavity. The intestines were adherent throughout, the cecum to the parietal peritoneum, and also to the bladder. Two large pus tubes and the ovaries were removed; all adhesions freed, and an artificial anus established. The pus pockets were opened and the cavity thoroughly flushed out with normal salt solution. She died three weeks later from general peritonitis. The autopsy showed a quantity of pus in the peritoneal cavity, a large collection being found directly beneath the liver. All the abdominal contents were adherent. Dr. John C. Da Costa reported two cases of ruptured ectopic gestation. In the first case, upon opening the abdomen he found black blood in the pelvis, the rupture in the tube being covered by the placenta, thereby saving the patient's life. When called to see the second case, he found the patient had absolutely stopped breathing. Artificial respiration, inhalations of oxygen and the intravenous injection of three pints of normal salt solution were practiced, after which breathing began, though the patient did not regain consciousness. An hour later a pint of blood was taken from the other arm and three more pints of saline solution injected. She improved, but later upon examination he found a hard mass over the bladder, in front of the uterus. Celiotomy was performed and an ectopic gestation of about three months standing found. Dr. Fisher reported a case in which ectopic pregnancy was present on both sides, in which the woman made a perfect recovery after operation. He states that an ectopic gestation may develop on the opposite side after it has appeared on one side. Dr. Erik called attention to the fact that where the hemorrhage is gradual the pelvis would be full of black clots. In speaking of puerperal sepsis, Dr. John C. Da Costa stated that indiscrete curettement is often responsible for the condition. He denounces the practice in women in whom labor was apparently normal. Dr. Fisher thinks curettement of the uterus after labor is only indicated when evidences of decomposition exist and advises packing the uterus with gauze after curettement. Dr. Devereaux reported a case in which the temperature rose to 106.4°, the pulse to 115 and respiration to 48. The urine was suppressed, the bowels constipated, and the patient very delirious. Large doses of whiskey and 1/30 of a grain of strychnine (every hour) were administered, also enemata and magnesium sulphate given. The patient recovered. The advisability of administering anti-streptococcal serum in this condition was discussed.

Dr. Malcolm Morris, Editor of the *Practitioner*, was in Philadelphia last week, and was the guest of honor at a reception given by Dr. John H. Musser.

Vital Statistics of Philadelphia for the week ending October 5, 1901:

Total mortality	392	Cases.	Deaths.
Inflammation of the appendix 1, bladder 2, brain 7, bronchi 6, heart 2, kidneys 12, lungs 25, pericardium 1, peritoneum 7, pleura 1, stomach and bowels 15, nerves 2, spine 1			82
Marasmus 18, inanition 14, debility 11			43
Tuberculosis of the lungs			49
Apoplexy 20, paralysis 7			27
Heart-disease of 15, fatty degeneration of 2, neuralgia of 2			19
Uremia 18, Bright's disease 6, diabetes 2			26
Carcinoma of the bowels 1, breast 2, stomach 2, uterus 2, jaw 1, esophagus 1, pancreas 2, rectum 4			15
Convulsions			10
Diphtheria 10	56		10
Brain-sclerosis of 1, softening of 3			4
Typhoid fever	79		9
Old age			5
Scarlet fever	53		3
Smallpox	40		6

Alcoholism 1, anemia 2, aneurysm aorta 1, burns and scalds 1, casualties 7, cholera infantum 14, cirrhosis of the liver 7, croup, membranous 2, cyanosis 4, diarrhea 5, disease, kidneys 1, drowned 1, dropsy 3, epilepsy 1, extra uterine pregnancy 1, gall stones 1, gangrene, senile 1, hemorrhage from lungs 1, hemorrhage from uterus 1, hernia 3, indigestion 1, insanity 1, leukemia 1, obstruction of the bowels 1, purpura hemorrhagica 2, rheumatism 1, septicaemia 1, sarcoma, breast 1, rectum 1, stricture of the esophagus 1, suicide 6, strangulation 1, syphilis 1, tetanus 1, tetanus, traumatic 1, unknown 1, whooping cough 4

81

NEW YORK.

Long Island College Hospital.—It is announced that George Foster Peabody will give \$50,000 for the construction of an operating-room in the Long Island College Hospital, as a memorial to the late Dr. A. J. C. Skene.

An Old Embalming Method.—The late Dr. Thomas Holmes, of Brooklyn, embalmed the body of President Lincoln, which was found to be in a most excellent state of preservation when viewed recently. His process was a radical departure from the ordinary mode of embalming by means of fluids. Dr. Holmes placed the body in a glass case and subjected it to pressure of a peculiar gas, the action of which hardened the flesh to a degree approaching the toughness of leather. That is all that is known of the process to-day.

St. Luke's Hospital, New York.—The directors of St. Luke's Hospital have cancelled their contract with the House of Rest for Consumptives, because the wards of the hospital have accumulated more tubercular patients than were desired. They have also determined upon the construction of a pavilion on the northwest corner of 113th street and Morningside avenue, to be devoted exclusively to private patients. Plans for the new building have been ordered. The sunlight and air to be had on Morningside Heights makes the site attractive to those who want private accommodations. The pavilion will be similar in appearance to those on either side of the main entrance. The cost is estimated at about \$300,000.

Professor Czerny, of Heidelberg, Germany, has been a guest of Dr. Roswell Park, at Buffalo.

The New York Juvenile Asylum, founded in 1851 to afford shelter for poor children, will in a few years be moved from its present site near Amsterdam avenue between 175th and 178th streets, as the directors have just acquired possession of 275 acres of land at Echo Hills, between the Hudson and Saw Mill rivers, on the line dividing Hastings from Dobbs Ferry. The property extends about 3600 feet along the New York and Putnam Railroad at Chauncey station, and includes the mountainous country running westerly to within 3000 feet of Broadway, being nearly half a mile wide. It is mainly wild land with a fine growth of trees and a small lake. On all sides are the country places of wealthy New Yorkers. Before the change is made, money for the project will be obtained by selling ground now owned by the asylum. The institution at present has about 1200 inmates.

Virchow Dinner.—To-night New York will celebrate the eightieth birthday of Dr. Rudolf Virchow, the noted pathologist, by a dinner given by his pupils, friends and admirers. Dr. William Osler, of Baltimore, will preside.

The Merchant Marine Hospital Service.—Dr. W. T. Jenkins, formerly Health Commissioner of New York city, is now in England, establishing a system of medical assistance for sailors, known as the Merchant Hospital Service. Each ship pays a membership fee of £3.—Doctor Jenkins says: "I make a contract to give to the members of the crews of ships, while at the different ports, medical and surgical treatment, to which quarantine laws do not apply, for \$15 for each ship, and this, I think, prevents any rebate. I have contracted for nearly 1,000 ships. My service covers thirteen or fourteen ports on the Atlantic seaboard. I will give medical attendance and visit the ship every day while she is in port, prescribe for the crew, and provide them with medicine. If a ship leaves a sailor

In the hospital, then the captain gives a pay order, but it would be my duty to see that he was discharged as soon as possible.

"A sailor is a carrier of disease, and if he does not get proper attention, he goes on and becomes a chronic invalid, and his progeny are probably affected and frequently become inmates of public institutions. We are trying to prevent that."

NEW ENGLAND.

New England Deaconess Hospital.—Plans are being made to build the New England Deaconess Hospital at Longwood, where a plot of ground has recently been purchased. The hospital is to be a structure of three stories and a basement, eventually to have three wings, one of which will be erected at once. There will be room for 120 beds, and the building will cost about \$100,000. As only \$24,000 have as yet been collected, a fair is to be held in Boston next month, when it is hoped that a large sum will be raised. It is probable that the first wing to be erected will be the surgical department. It will have wards with one, two, three, and four beds each, well equipped with modern appliances and furniture.

Tufts College Medical School.—The new building for the Tufts College Medical School was opened on October 3d. Dr. Elmer T. Capen, president of the college made the opening address. The building was then accepted by the trustees of the institution.

The City Emergency Hospital, Boston, Massachusetts. was opened to patients on the first of October. The hospital is three stories high, well equipped throughout, and has a roof-garden.

WESTERN STATES.

The Plague in San Francisco.—The fortieth patient died of suspected bubonic plague August 30, 1901. The autopsy showed a large left inguinal bubo with hemorrhage, in which plague bacilli were found. The heart muscle showed fatty degeneration and there were numerous plaques upon the aorta. One lung was edematous, the other congested. The spleen was enlarged and hemorrhagic; the kidneys small, soft, and congested. The mucous membrane of the stomach also showed hemorrhages. Animals inoculated died of typical plague. Four other suspicious cases and one death from the disease have been reported during September.

The Emergency Hospital, now in the course of erection in the Golden Gate Park, San Francisco, will be finished by January, 1902. It will have 60 beds, and will cost over \$8000.

Butte County Hospital.—The commissioners of Silver Bow County have decided to erect a new county hospital in Butte, Montana. It will cost about \$20,000.

The Utah State Medical Society held its annual meeting at Provo City, October 1-2, 1901.

Utah.—General W. J. Palmer and George Foster Peabody, former president and vice-president of the Rio Grande Western Railway, have given St. Mark's Hospital and the Hospital of the Holy Cross, Salt Lake City, each \$10,000, and have donated the sum of \$20,000 for the erection of four emergency hospitals in the mining districts of Sunnyside, Castlegate, Winter Quarters, and Cedar Creek.

New Mexico School Teachers.—In accordance with the new law that no person suffering from tuberculosis shall be allowed to teach school, 22 physicians have been appointed to examine school teachers of New Mexico.

Dr. Woodbridge Dead.—Dr. John Elliott Woodbridge, of Cleveland, whose peculiar views concerning the treatment of typhoid fever at one time kept his name prominent in the professional mind, died on August 31 at Bad Nauheim, Germany, from heart disease. Dr. Woodbridge was about fifty-five years old, and during the Spanish-American war was a volunteer surgeon in charge of the hospital at Fort Meyer.

An Aged Doctor Honored.—A banquet was given October 5th at the Auditorium Hotel, Chicago, by the medical profession in honor of Nathan Smith Davis, M. D., L. L. D., of Chicago. The colleagues of Dr. Davis united in this way to show their esteem and affection for one who has given his life to the uplifting of their profession. He was long ago dubbed the father of the American Medical Association, and held every position of honor within the gift of the association. He was its president in 1864-5. At Detroit

in 1874 it was ordered that a medal be struck, bearing Dr. Davis' likeness upon one side, and the name and date of the organization upon the reverse. Dr. Davis was born January 9, 1817, at Greene, N. Y. He began the study of medicine in 1834, and at his graduation wrote a thesis, "Animal Temperature," which was highly commended and selected to be read as a part of the commencement exercises. Dr. Davis is especially well known for his prominence and active interest in scientific organizations, being one of the founders of the Chicago Academy of Sciences, the Chicago Historical Society, the Illinois Microscopical Society, the Union College of Law and the Northwestern University. He was instrumental in organizing the State Medical Society of Illinois, and was its president in 1855. In journalism he is also well known. While in New York he filled the position of editor of the *Annalist*, and after moving to Chicago had editorial charge of the *Chicago Medical Journal*. Later he founded the *Chicago Medical Adviser*. He is the author of many medical works, the most notable being "A Lecture on the Effects of Alcoholic Drinks on the Human System, and the Duty of Medical Men in Relation Thereto." Dr. Davis is a Methodist, and is a member of Grace Church, Chicago. He has the peculiar habit of wearing on all occasions the white tie and swallowtail coat which characterized doctors in early days.

A New Phthisis Hospital in New Mexico.—St. Joseph's Hospital, an institution fully equipped for the practice of modern phthisis therapeutics has been established at Silver City under the charge of the Sisters of Mercy. Silver City possesses exceptional climatic advantages, the maximum annual rainfall being a little under 15 inches. The atmosphere is dry, summers are cool and winters warm, the result of an altitude of 6000 feet, making outdoor life practicable and comfortable all the year round. In this respect the climate of Silver City differs from El Paso, Tucson and other southwestern resorts, where the weather is enervatingly warm. The medical director is Dr. E. S. Bullock, former pathologist of the U. S. General Hospital for Tuberculosis, Fort Bayard, N. M.

A University Professor on the Philippine Board of Health.—Dr. Paul C. Freer, professor of chemistry at the University of Michigan, who was recently granted leave of absence for one year, has gone to the Philippine Islands to take charge of a branch department of the Board of Health. He expects to make a special study of tropical diseases, paying attention to typhoid, malaria, dysentery and plague, in which diseases the death rate in the Philippines is very high. It is probable that an improvement in the existing sanitary conditions among the natives will soon be noted.

SOUTHERN STATES.

University College, Richmond, Va.—A Pasteur Institute, in charge of Dr. A. G. Hoen, lately of the anatomical department of Johns Hopkins University, has been opened in the University College of Medicine, Richmond, Virginia.

Knoxville City Hospital.—The Knoxville City Council has appropriated \$2000 to finish the City Hospital, which will be ready for patients October 15, 1901.

Fire in a Soldiers' Home.—The Confederate Soldiers' Home, just east of Atlanta, Ga., was destroyed by fire, September 30. No lives were lost, but several narrow escapes were made. About seventy veterans were inmates of the building, some of them being invalids, who were rescued with difficulty. The loss is estimated at \$25,000, covered by \$22,000 insurance. The home, which was opened for the Confederate veterans of the state on June 30 last, was paid for by popular subscription.

The Baltimore Municipal Hospital.—On October 1, 1901, the Municipal Hospital Commission bought the Condon property on the Reisterstown road, as the site for the proposed hospital for infectious diseases. The price paid for the property, which consists of ten acres, was \$20,000. This leaves the Commission still \$5,000 from their appropriation. A letter has been sent to the Finance Commissioners requesting them to sell at once the old Quarantine property, the proceeds of which will be turned over to the commission. With this amount work will at once begin. The present frame building on the lot—the old Three-Mile House—is worthless and will be torn down. It is proposed to have four separate buildings—an admission building, a building for scarlet fever cases, one for cases of measles, and one for diphtheria cases. All the

buildings will set back from the road. The Western Maryland Railroad is in the rear of the property, and a station, to be known as the Municipal Hospital Station, will be established. There is also a small lake on the property. The commission regards the location as ideal for its purposes. As soon as the Quarantine property is sold, the Board of Awards will advertise for bids for the erection of the Municipal Hospital building. It was said that the owners of the property surrounding that bought for the hospital would protest, and, if necessary, go to court to prevent the establishment of the hospital there. The members of the commission claim there is absolutely no danger or reasonable objection that can be urged against the establishment of the hospital in the neighborhood.

The South Carolina Interstate and West Indian Exposition.—Dr. Manning Simons, one of the most distinguished physicians and surgeons in the South, has been elected medical director of the South Carolina Interstate and West Indian Exposition.

The New Medical Law of Texas.—Not only must future physicians of Texas pass a State Board Examination, but every physician who has registered since 1891 is compelled to show his diploma to the new Board of Medical Examiners, just appointed, in order to secure a license to practice. It seems that the law is being violated, unwittingly, perhaps, by undergraduates who act as assistants to a licensed physician. They often visit a patient for their chief, and while they are not paid by the patient, itemized accounts of their work are kept, for which a bill is duly sent out by the physician under whom they practice. Many of the undesirable, unlawful practitioners have already moved out of the state.

The Church Hill Medical Society, Richmond, Va.—The following papers will be read at the bi-weekly meetings of the Church Hill Medical Society this winter: Pneumonia in Infancy and Childhood.—Its Recognition and Treatment, by Dr. Garclu; Broncho and Lobar Pneumonia in the Aged.—Recognition and Treatment, by Dr. Parker; Pleurisy.—Its Varieties, Recognition and Treatment, by Dr. Blankingship; Croup, Simple and Membranous.—Recognition and Treatment, by Dr. Beazley; Acute Rheumatism in Childhood and Adults.—Its Symptoms and Treatment, by Dr. Virginius Harrison; Acute Tonsillitis.—Varieties, Symptoms and Treatment, by Dr. Barksdale; La Grippe, Complications, Varieties and Treatment, by Dr. St. J. Oppenheimer; Neuralgia, Varieties, Recognition and Treatment, by Dr. Gay; Acute Bronchitis.—Recognition and Treatment, by Dr. Cosby; Diphtheria.—Recognition and Treatment, by Dr. C. W. Massie; Measles.—Diagnosis and Complications, and Treatment, by Dr. Hord; Chicken-Pox.—Diagnosis and Treatment, by Dr. Collins.

MISCELLANY.

A Proposed Yellow Fever Institute.—The following announcement by Dr. Wyman explains itself. The object is one of such great importance that we quote the letter and memoranda in full.

Treasury Department,
Office of Supervising Surgeon-General,
U. S. Marine-Hospital Service,
Washington, D. C., September 13, 1901.

The Honorable, The Secretary of the Treasury.

Sir: I have to invite your attention to the subject of yellow fever, and to discussions which have been published in the medical journals and in the daily press during the past few months regarding its transmission. The subject is one with which the U. S. Marine-Hospital Service, through legal responsibility, has been intimately associated since its reorganization in 1871, the publications of this Service being the chief residuary of the statistics and other facts pertaining to this disease. The annual reports are largely devoted to this subject. In 1889 a volume was published entitled "Yellow fever, its nature, diagnosis, treatment, and prophylaxis, and quarantine regulations relating thereto," consisting of contributions by medical officers intimately acquainted with the disease, either by scientific or clinical work. A volume was published in the same year containing a report of a commission of medical officers detailed by authority of the President to investigate the cause of yellow fever. The Service, through its national quarantine stations and

cooperation with State and local stations, has many times prevented the introduction and, by its detention camps, the spread of the disease.

Within the last year a medical commission of the United States Army, operating in Cuba, has made a report, showing that the mosquito conveys yellow fever and declaring that this is the only method by which the disease is conveyed to man and that it is a particular species of mosquito only which thus transmits it. In their conclusions, it is stated that the cause of the disease is unknown. Based upon their findings, demands have already been made upon the Bureau for certain modifications of the quarantine regulations, which, for the present season, the Bureau, with its deemed justifiable conservatism, has declined to make, but the matter will undoubtedly again be urged during the next season and it is incumbent upon the Bureau to have definite scientific grounds upon which either to modify its present regulations or to maintain them. On the one hand the Bureau has no desire to perform unnecessary labor, nor to impose unnecessary restrictions upon commerce, its traditional policy being to maintain a scientific quarantine and to impose no restraints upon travel or commerce not demanded in the light of science and experience. On the other hand the Bureau can not, in the interest of commerce, remove time-honored measures without definite justification therefor.

Since the announcement of the findings of the above-mentioned army commission, the Service has continued the prosecution of its inquiries concerning this disease with special reference to the findings of this commission. This has been done not only in the hygienic laboratory, but by special orders transmitted to the officers assigned in April to the several fruit ports of Central America, to the medical officers in Cuba and Porto Rico, and to those at the southern quarantine stations of the United States. A number of reports have been received and published in the Public Health Reports containing facts of interest on the subject. To estimate these facts at their full value, to collect additional facts, and to give direction to future investigation, it has become necessary to devise a plan for a complete study of the subject in all its phases. This duty is incumbent on the U. S. Marine-Hospital Service by reason of the quarantine law of 1893, which provides for making the necessary quarantine regulations against this disease.

Section 4 of this law also requires—

That the Secretary of the Treasury shall also obtain, through all sources accessible, including State and municipal sanitary authorities throughout the United States, weekly reports of the sanitary condition of ports and places within the United States, and shall prepare, publish, and transmit to collectors of customs and to State and municipal health officers and other sanitarians weekly abstracts of the consular sanitary reports and other pertinent information received by him, and shall also, as far as he may be able, by means of the voluntary cooperation of State and municipal authorities, of public associations, and private persons, procure information relating to the climatic and other conditions affecting the public health.

That public health work of this character is incumbent upon the Service is further shown by the act of Congress approved March 6, 1901, in which an appropriation is made for a new building for hygienic laboratory, U. S. Marine-Hospital Service, the function of this laboratory, as stated in the law, being for the investigation under the Surgeon-General of contagious diseases and matters relating to the public health.

Moreover, Congress has provided a fund for the prevention of epidemic diseases which may be applied to this investigation, as there is no epidemic disease of greater importance as affecting the United States than this one.

In view of the foregoing facts, I have prepared and submit herewith a plan for the organization of a yellow fever institute in the U. S. Marine-Hospital Service, whose object will be to collect all facts concerning yellow fever, to designate the specific lines of investigation to be made, and to make the investigations. The members of this institution are to be the medical officers of the U. S. Marine-Hospital Service, and others specially qualified. They will be assigned for duty to one of four sections, each section having a special list of topics for consideration. Each of the four sections will be under the direction of one of the medical officers on duty in this Bureau and said Bureau officers, with the director of the hygienic laboratory,

the Surgeon General, and a secretary, will constitute an executive board, which is to have general oversight of all the investigations. This furnishes a convenient method of administration, as the machinery of the Institute will be readily operated in the Bureau, while the actual work will be carried on by members at various places.

At present, the Service work on yellow fever is being conducted by a limited number of officers working on more or less independent lines. The Institute provides for observation and experiment by a large number of workers in accordance with a general system—in fact, organizing and coordinating the work that has been going on and which is to be done.

The stimulus to the members will be not only the scientific interest in the subject, but the publication of their contributions in the shape of bulletins as often as it seems advisable to the board; and with the Department facilities and necessary funds for incidental expenses, it is believed that the organization will meet with a degree of success warranting its existence.

To illustrate the workings of the commission, in addition to the scheme of organization, there is inclosed a series of topics proposed for investigation in each of the four sections.

Respectfully, WALTER WYMAN,

Supervising Surgeon-General U. S. M. H. S.

Approved, September 25, 1901.

O. L. SPAULDING,

Acting Secretary.

ORGANIZATION.

Object.—The object of the Institute is to collect all facts concerning yellow fever; to designate the specific lines of inquiries to be made, and to make them.

Officers.—The Surgeon-General of the U. S. Marine-Hospital Service, ex officio, chairman of the institute; secretary, the medical officer in charge of the bureau division of scientific research.

An executive board to consist of the chairman and secretary, the director of the hygienic laboratory, and the medical officers in charge of the following bureau divisions, viz: division of domestic quarantine, division of foreign quarantine, and division of sanitary reports and statistics.

Duties of the Executive Board.—To direct the investigations, correlate the reports, and supervise publications.

Members.—Every medical officer of the U. S. Marine-Hospital Service and others specially qualified.

Sections.—Section A. History and Statistics.

Section B. Etiology.

Section C. Transmission.

Section D. Quarantine and Treatment.

Each section will be presided over by 1 member of the executive board. The chairman of each section will organize the work of the section, subject to the approval of the executive board. He shall direct operations and receive and classify its reports.

Members of the institute will be assigned to the class or classes for which they express a preference. These assignments, so far as medical officers of the U. S. Marine-Hospital Service are concerned, will be made with the approval of the Surgeon-General, and their duties under the direction of the section chairman shall not conflict with the regular duties and regulations of the U. S. Marine-Hospital Service.

Publication of the reports received from members will be made from time to time as determined upon by the executive board.

SECTION A.—HISTORY AND STATISTICS.

Topic 1. The early history of the disease.

Topic 3. History of recent epidemics (since 1850).

Topic 4. Relation to modern sanitation, especially paving, drainage, etc., in cities.

Topic 5. Why did not New Orleans have it in early times while Boston did?

Topic 6. Mortality statistics.

Topic 7. Maps showing yellow fever zones.

Topic 8. Maps showing the infectible territory in the United States.

SECTION B.—ETIOLOGY.

Topic 1. The cause of the disease.

SECTION C.—TRANSMISSION.

Topic 1. The transmission of the disease by the mosquito.

Topic 2. Can any other mosquito than the *stegomyia fasciata* carry the infection?

Topic 3. Is the progeny of the mosquito also infected?

Topic 4. How many generations?

Topic 5. Can the mosquito become infected by any other means than by sucking the blood of a patient sick with the disease?

Topic 6. Can the mosquito become infected by contact with the dried blood discharges or other infected materials upon fomites?

Topic 7. Can the disease be transmitted by any other means than through the mosquito?

Topic 8. Can the disease be conveyed by fomites, or through the air, soil or water?

Topic 9. The geographical distribution of *stegomyia fasciata* in relation to the disease.

Topic 10. Is the immunity enjoyed by certain localities due to the absence of this variety of mosquito?

Topic 11. A study of the life and habits of the *stegomyia* and allied species, especially with a view to their extermination.

SECTION D.—QUARANTINE AND TREATMENT.

Topic 1. Is disinfection of baggage necessary to prevent the spread of the disease?

Topic 2. Is any treatment of baggage necessary?

Topic 3. Mosquitoes in baggage, in merchandise, in cars, in ships.

Topic 4. Treatment of the patient.

Topic 5. Guards against mosquito bites.

Topic 6. Immunity of individuals, of races.

Topic 7. Individual prophylaxis.

Topic 8. Communal prophylaxis—sanitation.

Obligatory Vaccination.—Vaccination has been compulsory in Bavaria since 1807; in Sweden since 1816; in Württemberg since 1818; in Scotland since 1864; in England from 1867 up to ten years ago, when the famous "conscience law" was enacted; in Ireland since 1868, and in Germany since 1874. The German statistics include re-vaccination, which is also regulated by law. Those for the divisions of Alsace show the results obtained by compulsory vaccination. After a mortality of .21% from 1811 to 1875, when obligatory vaccination was first established, a mortality of .022% followed from 1875 to 1884. In Switzerland, vaccination was compulsory until 1883. In 1881, 7 deaths occurred from variola; in 1882, no deaths, but in 1883 there were 8; in 1884, 11; in 1885, 52, and in 1886, 85 deaths from smallpox. In England, with compulsory vaccination in 1889, there were 23 deaths due to smallpox, and in 1890 only 16. But in 1891 the deaths increased to 49; in 1892 to 431, and in 1893 to 1456. These statistics show the magnificent results of compulsory vaccination, which is as yet unknown in France. In the United States the regulations of the public schools make vaccination among children practically obligatory, but re-vaccination and the vaccination of adults are not compulsory.

Obituary.—Dr. W. G. Thornton, at Victoria, Texas, September 9, aged 47 years—Dr. Josiah A. Ireland, at Louisville, Ky., September 19, aged 77 years—Dr. Daniel E. Thayer, at Adams, Mass., September 29—Dr. Francis E. Hines, at Salem, Mass., September 30, aged 40 years—Dr. James W. Dunphy, at New York City, September 30, aged 26 years—Dr. W. F. McClure, at Jackman, Me., September 30, aged 35 years—Dr. James Walter Allen, at Lancaster, Pa., October 1, aged 48 years—Dr. A. T. Cherry, at Bowling Green, Ky., October 5—Dr. John F. Gudget, at Hazelton, Ind., October 5, aged 51 years.

Death of Dr. Shiveley.—Among the deaths from smallpox reported last week was that of Dr. George Shiveley, who died on Saturday, September 28th at the Municipal Hospital. Dr. Shiveley was 72 years old, a graduate of Jefferson Medical College, and in the fifties filled the position of resident physician at the Philadelphia Hospital. He discontinued practicing his profession about twenty-five years ago. He was a member of the Academy of Natural Sciences, a prominent Mason, and was identified with the Pennsylvania Historical Society.

GREAT BRITAIN.

A New Lunatic Asylum Near Aberdeen, Scotland.—On September 14th the foundation-stone of the hospital at the new asylum being erected by the Aberdeen City District Lu-

nacy Board at Kingseat, Newmachar, about 12 miles from the town, was laid.

Hospital Saturday in Belfast.—Saturday, September 14th was the day on which the annual collection was made for the Royal Victoria Hospital, Belfast, and it is announced that about £700 was realized, the amount for this year being the largest on record.

Obituary.—Dr. John L. W. Thndiehum died in London, September 7, 1901, aged 72 years. He was German born, having been graduated from the University of Giessen. At one time he held the position of lecturer upon pathological chemistry at St. Thomas' Hospital.

A New Tract in the Spinal Cord.—Dr. Purves Stewart, of the Westminster Hospital, London, has discovered a descending tract in the cervical region of the cord, ventro-external to the crossed pyramidal tract, yet separated by a distinct interval at the level of the tip of the lateral horn of the gray matter. It only reaches as low as the eighth cervical segment. Purves Stewart studied it in a patient with dislocation of the fifth and sixth cervical vertebrae, who lived ten weeks after receiving the injury.

Antivenene in India.—Every hospital and dispensary throughout the central provinces of India has been provided with antivenene. Nothing will more impress the natives than the recovery of a patient whom they know has been bitten by a deadly snake; nor will any person suffering from the bite of a snake be allowed to die in the future, without a trial of antivenene having been made.

The British Losses in South Africa.—An official report issued in London, October 5, shows that the British casualties in South Africa, from the beginning of the war to September 30, were 548 officers and 5,823 men killed in action, and 1,529 officers and 28,032 men wounded; 365 officers and 9,177 men are classified as missing or prisoners, of whom 354 officers and 8,471 men have either been released or have escaped. The deaths from disease and accidents numbered 10,738.

New Pathological Laboratory.—The opening of the new Pathological Laboratory of the University of Oxford will take place on Saturday, October 12th, at 3.30 P. M. Sir William Church, Bart., President of the Royal College of Physicians of London; Dr. G. Sims Woodhead, Professor of Pathology at the University of Cambridge, and others will take part in the proceedings.

A Beri-Beri Expedition.—The sum of £1000 has been given to the Liverpool School of Tropical Medicine by the Christmas Islands Phosphate Co. to defray the expenses of a scientific expedition for the investigation of beriberi. This company has also offered passage to members of the expedition on board a steamer which left Cardiff October 4. This ship will stop at Port Said October 18th. Sir John Murray and the Colonial Office have each contributed £100 in aid of the expedition.

Scarlet Fever in Birmingham.—The epidemic of scarlet fever now existing in Birmingham is much greater than any epidemic of the preceding five years. Two weeks ago there were 474 cases in the hospitals.

CONTINENTAL EUROPE.

Appointments.—Brussels: Following the retirement of Professor Rommelaere, Professor Stienon has become the director of the first medical clinic, Professor Destree having been appointed director of the second.—Charkow: Dr. S. Delizyn has been appointed extraordinary Professor of Operative Surgery.—Erlangen: Dr. Ernst Graser, Professor of Surgery at the Rostock Medical School, has been appointed Professor of Surgery at the University of Erlangen, replacing the late Dr. von Heinecke.—Heidelberg: Dr. K. Brauer has been made extraordinary Professor of Medicine. Dr. Ferdinand Petersen, of Surgery, and Dr. Siegfried Bettmann, of Dermatology. Vienna: Dr. Ernst Finger has been appointed extraordinary Professor of dermatology, and Dr. Hans Rabi, extraordinary Professor of histology.—Kasan: Dr. A. G. Agababow has been appointed Professor of Ophthalmology.—Prague: Dr. Andreas Schurtz has been appointed extraordinary Professor of the History of Medicine and of Epidemiology at the Bohemian University of Prague. Copenhagen: Dr. K. B. Pontoppidan has been appointed Professor of medical jurisprudence and hygiene, in the place of Dr. Jaedeken.—Lund: Dr. M. J. C. A. Forssmann has been appointed professor of pathology.—Groningen: Dr. H. J. Hamburger, of Utrecht

has been appointed professor of physiology, replacing Dr. Hulzinga.—Leyden: Dr. G. C. van Walsem has been appointed professor of pathological anatomy, in the place of Dr. Slegenbeek van Heukelom.—Koenigsberg: Dr. Itelnhold Unterberger, physician in charge of the Charity Hospital, has been granted the title of professor.—Warsaw: Dr. E. Negnamow of Charkow has been appointed professor of ophthalmology.

Foreign Obituary.—On August 25, 1901, Dr. Cuneo, Inspector-General of the French Marine Hospital Service, died at Vlehy, aged 67 years. He was Commander of the Legion of Honor and President of the Upper Council of the Marine Hospital Service. At Blankenberghe, Belgium, Dr. Adolf Fick, Privy Councillor and Professor of Physiology at the University of Würzburg, on August 21, 1901. Dr. J. Rubio y Giles, Professor in Seville.—Dr. Alfred Vaucher, formerly Professor of obstetrics and gynecology in the medical school at Geneva, Switzerland.—Dr. Galiani, Professor in Athens.

The Fifth International Congress of Physiology was held from September 17th to September 21st in the physiological laboratory of the University of Turin, under the presidency of Professor Angelo Mosso. The assembled physiologists were formally welcomed by the president in a short address. Sir Michael Foster, K. C. B., M. P., secretary of the Royal Society, was then elected honorary perpetual president. Professor Fano, Professor Fredericq, Professor Grützner, and Professor Sherrington were appointed general secretaries. More than 200 physiologists from various countries were present, and 186 communications were announced.

The Thirteenth International Congress of Medicine.—The General Secretary of the Thirteenth International Congress of Medicine, which was held in Paris, August 2-9, 1900, requests any member who has not yet received all the proceedings of the Congress, to write at once to the editors of the Congress, Masson & Cie., 120 Boulevard Saint Germain, Paris. The proceedings consist of one large volume and seventeen smaller ones containing the records of the separate sections. Claims for these books will not be acknowledged after the 31st of December, 1901.

A Giant Child.—A child of three years was recently exhibited at a medical society meeting in Berlin, who was 3 feet 8 inches high, and weighed 19½ pounds. His feet and hands are large, and his mouth is generally open. His penis measures 2½ inches in length, his pubis is covered with hair, and his testicles are as large as pigeons' eggs. He began to grow at the age of 18 months. He is not particularly intelligent.

French Marine Hospital Service: Dr. Auffret, director of the Marine Hospital Service in Brest, has been appointed Inspector-General of the Marine Hospital Service in France, replacing the late Dr. Cunéo, whose death occurred a few weeks ago.

The Nobel Prizes.—These two prizes, amounting to 200,000 crowns, approximately \$56,000 each, have been awarded to Dr. Finsen, the Danish physician who invented the apparatus for the medical treatment of lupus by electric light, and to Dr. Pawlow, the Russian physiologist, whose work upon nutrition is well known.

The New Staff Surgeon-General of the German Army.—Dr. Rudolf von Leuthold, First Physician to the German Emperor, has been appointed Staff-Surgeon-General of the German Army, replacing the late Dr. von Coler. Surgeon-General von Leuthold received his professional education at the University of Berlin. He has for many years held the post of Professor of Military Surgery in the Kaiser-Wilhelm Academie and was also editor of the *Deutsche Militärärztliche Zeitschrift*.

Sanatorium at Belzig, Germany.—An anonymous benefactor has promised to defray the cost of erecting a building with a capacity for 30 children, in the grounds of the Sanatorium of the Berlin-Brandenburg Sanatorium Association at Belzig.

Nothnagel's Sixtieth Birthday.—On September 28, 1901, occurred the sixtieth birthday of Professor Hermann Nothnagel, director of the first medical clinic in the University of Vienna. This will be appropriately celebrated by his former students about October 15. The committee having the affair in charge consists of Drs. H. Lorenz, J. Manna-berg, and Robert Breuer.

1. Leishman describes a simple and rapid method of producing Romanowsky staining, which for ordinary blood staining for the examination of smear preparations from bone marrow, from glands such as the spleen and liver and from cancer juice and as a selective tissue stain for sections, appears to present many advantages. A 1% solution of mediate methylene blue (Grubler) in distilled water is made and then rendered alkaline by the addition of 0.5% of sodium carbonate. The solution is then heated to 65° C. in an oil stove for 12 hours, and afterwards allowed to stand at room temperature for 10 days. A 1 in 1000 solution of eosin, extra B. A. (Grubler) in distilled water is also prepared. Equal volumes of these 2 solutions are mixed in a large open vessel and allowed to stand for from 6 to 12 hours, being stirred from time to time with a glass rod. The abundant flocculent

precipitate which results is then collected on a filter, thoroughly washed with distilled water until the washings are colorless or have only a pale blue tinge, and the insoluble residue carefully collected, dried and powdered. The resulting powder, which has a greenish, metallic luster, contains the active staining ingredient in Romanowsky's method. The best solvent for this new dye is pure methyl alcohol (Merck's "for analysis.") The powder is dissolved in the proportion of 0.15%, and the resulting solution kept in stoppered glass bottles until required for use. Three or 4 drops of the stain are allowed to fall upon the blood film, which should be prepared in the usual way. No attempt is to be made to check evaporation. After about one-half minute, double the quantity of distilled water—that is, 6 to 8 drops—is added and allowed to mix with the alcoholic solution of the dye-stain and the film is stained for 5 minutes. The stain is now gently washed off with distilled water, and a few drops of the water are allowed to rest on the film for one minute, at the end of which time the specimen is ready for examination, either directly in water under a 1-6 or 1-8 inch objective, or, after drying (without heat) and mounting in xylol balsam, under an oil-immersion lens. [J. M. S.]

2.—When stained by Neisser's differential stain, the Klebs-Löffler bacillus will show the blue granules, even when it is growing with difficulty owing to the synchronous growth of other bacteria. The observations of Heaton, Caiger and Pakes concern 100 cases, with the following results: Clinical and bacteriological diagnosis both positive, 53; clinical and bacteriological diagnosis both negative, 17; clinical diagnosis positive, bacteriological diagnosis negative, 25; clinical diagnosis negative, bacteriological diagnosis positive, 5. The authors feel convinced that if coverslip preparations are made directly from the throat without the loss of any time, this number of positive results will be increased. As a result of their observations, they feel that Neisser's stain is a valuable one in several ways: (1) Because a positive diagnosis is rendered more certain for those who cannot be considered as experts, since it is often easier to diagnose the Klebs-Löffler bacillus after staining by Neisser than after staining by ordinary methylene blue. (2) Because a trustworthy positive result may be obtained from the microscopical examination of a preparation made direct from the swab. (3) Because the use of Neisser's stain does not appear to introduce any fallacy not found in the application of other methods. [J. M. S.]

3.—E. Collingwood Andrews reports two successful cases of operation for perforated gastric ulcer. In both of the cases there was considerable food in the stomach at the time of operation, and it was impossible to empty the stomach through the pyloric opening. The constant pouring out of the stomach contents through the perforation rendered its closure difficult. Andrews makes it a rule to irrigate, if the contents of the stomach are widely diffused, but is satisfied with careful sponging, if the escape is moderate and limited. The first patient was a young woman, 23 years old, who had suffered for some months from indigestion. She had never vomited blood. The symptoms of perforation were ushered in by a collapse which took place suddenly while the patient was carrying a tray. The patient suffered extreme pain; the abdomen was board-like and exquisitely tender. The abdomen was opened within a few hours and a perforated ulcer found near the cardiac end of the lesser curvature. The opening was closed with two Lambert sutures and the cavity washed out with saline solution. Both a drainage tube and gauze were used. The gauze drain was removed on the second day and the drainage tube on the third. On the fifth day there was a free action of the bowels after an oil injection and the patient was allowed milk by the mouth. The recovery was uneventful. The second case was that of a gentleman 30 years of age. In this case also the onset of symptoms was sudden and violent. When seen by Andrews, two hours after the first symptom, the patient was found in a collapsed condition. The abdomen was rigid and distended and liver dullness was obliterated. Immediate operation was performed. A perforation was found on the lower border of the stomach $\frac{3}{4}$ of an inch from the pyloric orifice. In this case the escape of stomach contents was more or less limited and for cleansing only sponging was employed. A combination of tube and gauze drain was

used as in the other case. The patient was fed per rectum for seven days; the gauze drain was removed on the second, and the tube on the sixth day. Excepting a phlebitis in the right leg the recovery was uneventful.

[J. H. G.]

4. The pathology of pneumococcus infection is concerned with many cases of disease which, in their clinical aspects may have little in common, and in their morbid anatomy might vary as widely. The specific organism of this infection, the pneumococcus, micrococcus pneumoniae or diplococcus lanceolatus, belongs to the class of strict parasites, so far as our present knowledge goes. It occurs as infecting man alone, and has not yet been found as a parasite of the lower animals. It has been but rarely met with outside the human body. The organism exists as a parasite on the mucous membranes of perfectly healthy individuals, infesting more especially the mouth. It is also found in the anterior nares, in the conjunctival sac and in the vagina. Micrococcus pneumoniae, although not found occurring naturally in the lower animals, is actively pathogenic for many of them. This susceptibility is most marked in the rabbit, least in the dog. In testing the organism as obtained from healthy saliva, its virulence for the rabbit will usually be found quite as well marked as the virulence of a strain isolated from a case of pneumonia. When, therefore, the parasite becomes pathogenic for its human host, there is no reason to suppose that infection has happened because of any sudden access of virulence to a previously harmless parasite; but rather, it is probable that the condition of the host has afforded opportunity, which was usually wanting, under the conditions of ordinary good health, for the exercise of a natural pathogenic power. With regard to the exact nature of the toxic substances which are produced in the course of pneumococcus infection, very little is known. The action of the pneumococcus toxins on particular tissues as manifested by histological changes, is also but little known. The simplest form of pneumococcus infection is that resulting from a poisoned wound of the subcutaneous tissues; a localized abscess, or a more or less spreading cellulitis. The first point that has to be considered in connection with the fibrinous lobar pneumonia which results from pneumococcus infection is whether the pneumonia is merely a manifestation of a general infection, or whether it represents a purely local infection. Foulerton thinks that the evidence available shows that the lung infection is usually the primary condition, and that any blood infection is secondary to this. With regard to the actual causation of fibrinous lobar pneumonia, and looking upon the lesion as produced by a local infection of the lung, it is quite likely that the old belief that a chill or exposure to cold has an influence is well founded. There is no doubt that exposure to cold may produce some temporary congestion of the capillaries of the lungs, and under these conditions it is quite likely that there is just sufficient alteration in the state of the cells lining the air vesicles to render them less efficient in resisting invasion by any bacteria which may come to rest on them. The author thinks that what is known as epidemic pneumonia is not caused by the micrococcus pneumoniae. Fibrinous lobar pneumonia is not, of course, the only result of pneumococcus infection of the lung; there is a pneumococcus bronchopneumonia, especially in children, and the pneumococcus perineurular pneumonia found in cases of pulmonary phthisis. The initial pleural effusion which occurs to a greater or less extent in probably every case of lobar pneumonia is, in the majority of cases, due at first to the irritation of toxins passing through from the neighboring infected portion of the lung, and not to the presence of cocci themselves in the pleural sac. In children the pleural lesion is frequently a primary one. Considering how well cases of empyema in children do under surgical treatment, it is difficult to believe that there is a lobar pneumonia, underlying any large proportion of them. Bacteriologically there is a marked difference in the causation of pleural empyema in children and in adults. The two parasites which cause a very large majority of all the cases of empyema which the author has examined are the streptococcus pyogenes and the micrococcus pneumoniae; but in spite of the obvious connection clinically between empyema and pneumonia in adults he finds that

75% of the cases in adults are caused by the streptococcus pyogenes and 25% only by the micrococcus pneumoniae, whereas, in children, at least 75% of the cases were caused by micrococcus pneumoniae and about 25% by the streptococcus pyogenes. When the details of published cases are considered it is seen that the joint affection may take one of 3 forms: It may be purulent from the outset, it may be at first sero-fibrinous and then purulent, or it may remain sero-fibrinous, in the last case assuming sometimes the type of an osteo-arthritis with neighboring tenosynovitis. A pneumococcus meningitis may be acute and purulent, or chronic and sero-fibrinous. The purulent form may be the only lesion that is found due to the infection, and apparently the primary one, and in that case it is possible that the infection occurred by way of the nose. Peritonitis, caused by pneumococcus infection may be sero-fibrinous or purulent. It is most frequently met with in children. Nothing definite can be said concerning the possibility of an acquired immunity in man after a pneumococcus infection. Washburn believes that the pneumococcus exists in Nature outside the body of animals, but in an avirulent form, which, under certain conditions, may become virulent. Bryant is strongly of opinion that cases of so-called idiopathic peritonitis, if examined bacteriologically, will prove to be pneumococcal. Clarke said that the production of endocarditis is best known as the consequence of general infection in pneumonia, but that it is occasionally found under other circumstances, when the source of infection was uncertain. Eyre stated that he is now able to demonstrate experimentally that the same strain of pneumococcus can, by varying the conditions of the experiment, be made to provoke tissue reactions belonging to either the fibrinous or the edematous group. The predominant features of the lesions produced by the pneumococcus depend on at least 2 factors, namely, the virulence of the infecting pneumococcus and the individual resistance of the subject infected. Fisher had seen 5 cases of abscess of the lung as a complication of pneumonia. [J. M. S.]

5.—Lazarus-Barlow reported two cases of posterior basilar meningitis; one in a female child, aged 1 year and 5 months; and the other in a female, aged 9 months. There was not a trace of tuberculosis in the body of either infant. No micro-organisms could be found in coverslip preparations of the cerebrospinal fluid or the inflammatory material at the base of the brain in either case. On cultivation, however, an organism was obtained that presented characters fully compatible with the micrococcus pneumoniae of Fränkel. [J. M. S.]

6.—Bryant reports 3 cases of pneumococcus peritonitis; one in a girl, aged 5 years; another in a man, aged 45 years, and the third in a girl, aged 4 years. Pneumococcus peritonitis may be classified in two ways: (1.) Primary, when the peritoneum is the first structure to be involved, and (2.) secondary, when the peritoneum is infected as a complication of some other pneumococcus lesion. Or according to the distribution: (1.) Local or encysted, and (2.) general or diffuse. In the general or diffuse form the abdomen is distended, partly from the presence of fluid in the peritoneal cavity and partly from tympanitic distension of the intestines. On opening the peritoneal cavity a fair amount of turbid, light, greyish-yellow fluid may be found. If this is collected and allowed to stand, the upper portion becomes much clearer and a thin pale, greyish-yellow deposit of pus cells and flakes of lymph falls to the bottom of the glass. Coverglass preparations of the pus stained with Macdonald's stain show the presence of capsulated diplococci. The peritoneum, both visceral and parietal, is covered with pale yellow flakes of lymph and coils of intestine may be adhering to each other and to adjacent viscera. The lymph peels off with ease, leaving a slightly dull surface, and the peritoneal blood vessels are found to be congested, dilated, and distended with blood. In virulent infections there may be actual extravasations of blood. In the local or encysted variety a similar condition of a portion only of the peritoneal cavity may be seen, and the parts most likely to be involved are the upper surface of the liver, the upper surface of the spleen, the pelvic cavity, and occasionally the right iliac fossa. In some cases the lymph is very thick and there is little fluid. As a rule, there is no obvious primary focus to be discovered in the abdomen to account for the peritonitis. Pneumococci are frequently found in the mouths and throats of

healthy people, and therefore must be constantly swallowed with the saliva and food. If there is severe gastro-intestinal disturbance there will be not only a general lowering of the resistance of the body, but also an altered condition of the gastro-intestinal secretions. Such a series of changes might well predispose to the growth and development of the pneumococcus in the gastric and intestinal mucosa, and might also allow of the passage of the organisms by means of the blood vessels and lymphatics to the peritoneum. The very large proportion of girls to boys affected by this form of peritonitis is very suggestive that the uterus and Fallopian tubes are the channels by means of which the pneumococcus gains access to the peritoneal cavity. It is not easy to explain, however, why it is that, when adults are attacked, they are nearly always men. There is no doubt that many cases die as a result of a general pneumococcus septicemia. Case 1 appears to have been an example of a general blood infection. In Case 2 the clinical evidence points to primary infection of the peritoneum, with a secondary implication of the pleura, which may have been due to a general blood infection, or to a local infection through the lymphatics. Case 3 died from pneumococcus septicemia, pneumococci having been concentrated in the heart, blood, spleen, peritoneum and pleura. The clinical and pathological evidence pointed to the peritoneum as the first structure to be involved, the pleura, probably, being infected soon after. Very frequently when making post-mortem examinations it is found that the upper surface of the liver is firmly attached to the under surface of the diaphragm by means of fine fibrous adhesions, and that the base of the right lung is also fixed to the upper surface of the diaphragm in a similar manner; on the left side the spleen and base of the left lung may be similarly attached to the diaphragm. The author is of the opinion that the majority of these cases are examples of cured local pneumococcus peritonitis, the primary lesion being pneumonia or pleurisy, and the peritonitis being caused by a secondary infection through the lymphatics. The skin is another possible channel by means of which the pneumococcus can reach the peritoneum; but there have been no cases published as far as the author knows, which point to this manner of infection. [J. M. S.]

7.—Gley concludes that **exophthalmic goiter** is due to an alteration in the thyroid apparatus involving, in the first place, the parathyroid, the normal function of which is disturbed. [J. M. S.]

8.—Whether the causation of **exophthalmic goitre** is primarily in the nervous system or in the thyroid gland, there can be no doubt that the abnormalities, wherever they may be, are of a chemical nature. Edmunds has recently been making some experiments with a view of determining the nature of the changes in the central nervous system caused by total excision of the thyroid and parathyroids. The cord and medulla, and in one case also a portion of the brain from dogs were examined by Nissl's method. The Nissl bodies were no longer defined and the chromophilous elements had undergone chromatolysis. Cells were found in every stage of destruction. These changes are very similar to those described by Mott as occurring in some forms of acute poisoning. In fact it appears that athyroidism is a form of acute poisoning affecting the central nervous system. It seems probable that the absence of the parathyroid secretion is in some way the cause of the acute symptoms, and, from the nature of the changes in the cells, it seems that its presence is necessary to the extraction from the blood and deposition in the cells of the Nissl bodies, which are supposed to be the food of the cells. [J. M. S.]

9.—Eyre describes a new **centrifuge for bacteriological work**. [J. M. S.]

10.—Foulerton and Hillier examined the urine from 25 cases of more or less chronic tuberculous, pulmonary phthisis, in each of which the bacillus tuberculosis was found in the sputum. The inoculations were carried out as follows: One hundred and fifty cc. of the 24 hours' excretion were centrifugalized and 5 cc., containing any sediment present, were pipetted off from the bottom of the tube. Of these 5 cc., 2 cc. were injected into the popliteal space of each of 2 guinea pigs. Of 18 patients suffering from more or less chronic, tuberculous, pulmonary phthisis,

the urine contained the bacillus tuberculosis in 9. In 6 of these 9 cases the absence of tuberculosis of the urinary tract was proved by post-mortem examination, and there was no reason to suspect that the condition existed in any of the other 3. So far, therefore, as we can generalize from a series of only 18 cases, we can say that the urine of 50% of fairly advanced cases of tuberculosis, pulmonary phthisis contains the bacillus tuberculosis, such organisms being in a virulent condition for the guinea-pig. A general blood infection, as evidenced by the presence of bacilli in the urine, is more common in cases of tuberculous pulmonary phthisis than is commonly supposed. When the bacillus tuberculosis invades the blood in cases of pulmonary tuberculosis, it does so usually in extremely small numbers, and there can be but little tendency for it to multiply there, but any occasional bacilli that may get into the blood stream are eliminated by the kidneys; these glands showing only a slight tendency to become infected in the of fairly advanced cases of tuberculous, pulmonary phthisis process. It seems probable that in cases of pulmonary tuberculosis the patient is often gradually undergoing a process of auto-immunization, and that after a time the tissues generally are less susceptible to infection than they were when the primary infection occurred; and it is only on this assumption that we can explain the fact that, considering the frequency with which the specific bacilli apparently obtain access to the circulating blood, dissemination of the tuberculosis is comparatively uncommon in the chronic, tuberculous, pulmonary phthisis of adults. The authors were unable to detect any difference between animals inoculated with tuberculous urine and control guinea-pigs inoculated from healthy urine, showing that the urine of tuberculous patients is not increased in toxicity. [J. M. S.]

11.—One of the commonest lesions found in the liver in conditions of toxemia is the presence of more or less extensive areas of **necrosis of the liver cells**. A second well-marked characteristic is the fact that the columns of liver cells are markedly separated from each other. There are also changes to be noticed in the liver cells that are not actually necrotic. There is a marked vacuolation of most of the cells and an evident tendency to division among the nuclei. Reexner has shown, by means of injected specimens, that the more intense capillary lesions take place within the areas of necrosis, and considers that in these capillary lesions the main cause of the necrosis is to be found. In spots where the capillary wall is a little more damaged than elsewhere, the lymph which bathes the cells becomes more concentrated and thus the cells are immersed in a bath of poison, and their functional activity being destroyed, they die. Such seems to Longridge the most feasible explanation of the focal character of the lesion. No casual relationship has been made out between the necrotic spots and typhoid bacilli. [J. M. S.]

12.—When the subject is reviewed with an open mind the view that **rheumatic fever** is due to a diplococcus infection is the one which has met with the greatest support. Roynton and Paine believe that very shortly, if not already, an advance can be made from the position that rheumatic fever is due to **bacterial infection**, to the position that it is due to **diplococcus**. The exact place that the diplococcus will take in the coccus group may take some time to ascertain with certainty, but it seems more likely to lead to advance in our knowledge if we look upon it as specific, rather than if we regard it as an attenuated form of some other coccus infection. In the history of rheumatic fever heredity takes such a prominent place, and the rheumatic constitution is so clearly recognized, that it is hard to escape from the conviction that the disease is not to be explained by the presence and nature of the micro-organism only, but that in addition there must be some condition of the human tissues which also is of importance. [J. M. S.]

13.—The average hemoglobin value of the **red blood corpuscles** was 117 in men and 105 in women. By regarding 117 as the normal, and calling this 100, the hemoglobin value of the corpuscle in woman's blood is 89.7. Goldsmith found an average of 4,860,000 corpuscles per cc. from a series of healthy males and 4,350,000 in the series of females. The average value of 5 mm. of precipitated corpuscles alone was 80 in men. The average count of the precipitated corpuscles

was 12,000,000. The average hemoglobin value of the corpuscle equals 100. In females the average value of 5 cmm. precipitated corpuscles alone was 81. The average count of the precipitated corpuscles was 13,500,000. This gives an average hemoglobin value of 96.6, or corpuscle for corpuscle male and female 100 to 86.5. The average relation of corpuscle to plasma was 37% in men; the average relation of corpuscle to plasma was 39¼% in women, that is to say, under similar conditions a similar number of women's corpuscles will occupy a smaller space than a similar number of men's, and that the average corpuscle in women is smaller than in men; roughly, their bulk is as 11 to 8. [J. M. S.]

14.—Nuthall and Hunter have studied the bacteriology of cerebrospinal meningitis. They conclude: (1) That in 10 cases of meningitis a diplococcus was isolated from the cerebrospinal fluid obtained by lumbar puncture during life. (2) That this diplococcus agreed in its morphological and biological characteristics with the diplococcus intracellularis meningitidis of Weichselbaum. (3) That the diplococcus occurred in 2 slightly different forms, types A and B. (4) That in some cases the diplococcus was present in pure culture, in others associated with other micro-organisms—for example, bacillus influenzae and bacillus tuberculosis. (5) That the clinical picture and pathological changes found in these cases were those met with in posterior basal meningitis. (6) That in all probability posterior basal meningitis is a sporadic form of cerebrospinal meningitis, and is caused by the same micro-organism, the diplococcus intracellularis meningitidis of Weichselbaum. (7) That in the majority of the cases it was impossible, from the clinical aspect alone, to make a correct diagnosis of the variety of meningitis present. [J. M. S.]

15.—Flexner has had opportunities of making a comparative study of several cultures of bacilli obtained from cases of dysentery. These organisms are designated Manila cultures, Kruse's bacillus, Shiga's bacillus, cultures of a Porto Rican and Strong's bacillus. The differences of growth are slight, and probably depend upon purely accidental circumstances. A comparison of the morphology of the bacilli shows only very minor differences. Kruse has not observed motility at any time in his culture; Shiga states his to have been feebly motile, while those of the author were at first slightly motile, but soon became quiescent in artificial cultivation and did not regain motility. Strong's observations coincide with the author's. Vedder and Duval, under the direction of the author, have succeeded in demonstrating flagella by Van Eppengheim's method in several cultures. The serum reactions have been of the greatest importance, and are, moreover, unmistakable in significance; they indicate close relationship between the bacilli from Japan, Manila, Porto Rico, and Germany, and they further render probable the identity of the epidemic dysentery of this country with that of the East and Germany. [J. M. S.]

17.—Hunter concludes: (1) That the bacillus coli communis and a few other micro-organisms possess the power of reducing neutral red to a canary yellow fluorescent color. (2) That the bacillus typhosus never possesses this power of reduction. (3) That it is possible within 12 to 21 hours to diagnose with accuracy by means of neutral red, the typhoid group of micro-organisms from the true colon group. [J. M. S.]

18.—The question of the number of cases of typhoid fever in which the intestinal lesions are absent has been approached from the bacteriological side in 20 instances. In all but 5 or 6 of these cases the investigators have not sufficiently differentiated between the typhoid and the colon bacillus. Lazarus-Barlow report the case of a child, aged 13 months, who was one of a family of 7 individuals of whom 6 suffered from typhoid fever. He was admitted on the sixteenth day of the disease with diarrhea, bronchitis, abdominal distension and rose spots. The spleen could not be felt. Widal's reaction was given in a 1 in 100 dilution in less than 15 minutes, and in a 1 in 50 dilution immediately on the seventeenth day of the disease. At the post-mortem examination there was not the slightest trace of any ulceration, either recent or old, in the intestines. From the spleen of the child, more than one kind of bacillus was obtained. Ultimately the number of

varieties was reduced until 6 were obtained which were certainly either colon bacilli or typhoid bacilli. One of these 6 was ultimately adopted as the true typhoid bacillus because of the positive manner in which it reacted to the tests available for distinguishing between bacillus coli communis and bacillus typhosus. The weakest point in the chain of evidence is in reference to the agglutination test, which required a dilution of 1 in 200, with a serum which agglutinated an undoubted typhoid bacillus in a dilution of 1 in 2000. [J. M. S.]

19.—There are 3 micro-organisms of the genus coccus which play an important role in the pathology of the skin. The first is the streptococcus of Fehleisen, the special cutaneous lesion produced by which is the impetigo contagiosa of Tilbury Fox. The second is the staphylococcus aureus of Rosenbach, the special cutaneous lesion produced by which is the follicular orificial pustule of the impetigo of Bockhart. The third is a grey colored staphylococcus (morococcus of Unna), the special lesion produced by which is pityriasis simplex wherever situated. In the course of streptococcus septicaemia the bullae of infectious pemphigus may arise, and lumps may develop in the skin similar to those of erythema nodosum, which are the result of streptococcus thrombi in the blood vessels of the derm. Direct inoculation of streptococci into the derm may produce erysipelas. The streptococcus may cause dermic ulcerations deeper than mere epidermic erosions. The proper treatment of streptococcal lesions of the epidermis is the local application of solutions of the sulphates, for example, zinc sulphate, 1 gm., distilled water, 100-200 grams. The local remedy for pustular lesions produced by the staphylococcus aureus is sulphur; for example, alcohol 30 gm., precipitated sulphur, 19 gm., rose water, 100 gm. The best topical remedy against the grey-colored staphylococcus and the pityriasis that it causes is coal tar combined with the mercurial peroxide; oil of cade 19 gms., yellow mercury binoxide 1 gm., yellow vaseline 30 gm. Galloway believes that there are 2 elements of difficulty in investigating the bacteriological character of cutaneous lesions. The first is that lesions produced on the skin are rarely the result of one single factor, nor of one single organism; mixed infections are probably the rule. The second difficulty in the way of obtaining trustworthy results is that of bacteriological technique, and especially of obtaining cultures which contain the pathogenic organism and not the normal or accidental flora of the skin. Savill has procured some streptococcus vaccine and with it treated a severe case of furunculosis. The patient had suffered from the boil for 3 months, but after 3 hypodermic injections at intervals of a few days a complete cure was obtained. This does not altogether correspond with the bacteriological results which attributes boils to a staphylococcus infection. [J. M. S.]

20.—Dubreuilh reports a case of Paget's disease of the vulva. [J. M. S.]

21.—MacLeod believes that yaws and syphilis are different histological entities. (1) Because the plasma cells are not so definitely clustered around the vessels in yaws as they are in syphilis, nor do they ever form foci suggesting a tuberculous nodule, as they occasionally do in the latter disease. They are seldom arranged in rows, which frequently occurs in syphilis. Large multinuclear cells (chorioplakes) and true giant cells, which may be present in syphilis, are absent in yaws. No hyaline degeneration, such as may be found in syphilis, is detected in the plasma cells. (2) Because the rarefaction of the collagen is more marked in yaws than in syphilis; organization is not detected, and colloidal degeneration such as occurs in a syphilitic gumma, is absent. (3) Because there is no tendency to thickening of the vessel wall or to endothelial proliferation, such as so frequently prevails in syphilis. (4) Because the proliferative changes in the epidermis in yaws are only equalled in syphilis in the condylomata, while the marked tendency of the stratum corneum (hyperkeratosis), which is an invariable characteristic in yaws, is unusual in syphilis. [J. M. S.]

22.—In discussing the nature of the disease known as erythema induratum scrofulosorum Whitfield expressed the opinion that there were at present 2 diseases described under the same name, one of which was a tuberculosis of

very slight severity, while the other had no relation to tuberculosis at all. [J. M. S.]

23. Heatty reports a case of *pityriasis rubra pilaris*. [J. M. S.]

24. Fox and McLeod conclude (1) That *parakeratosis variegata* is a clinical entity. (2) That it affects chiefly the male sex, usually occurs in adult life, and the patients are generally in robust health when attacked by it. Little is known of its etiology, though from its general configuration and histology it suggests a vaso-motor disturbance associated with edema and infiltration of cells in the corium and secondary changes in the epidermis. (3) That the initial lesion is a macule, or a maculopapule of small size, flat on the surface, and covered with a fine adherent scale, which may be scratched off without causing bleeding. (4) That by the coalescence of the lesions a peculiar retiform arrangement results, in which areas of normal skin are enclosed, and which, combined with differences in the color of the lesions in the more dependent parts of the body, produces the marbled or variegated appearance, which is one of the most pronounced characteristics of the dermatitis. (5) That it affects the skin almost universally, except as a rule that of the face, scalp, palms, and soles. (6) That it is subject to remissions and exacerbations, but is peculiarly chronic in its course. (7) That marked subjective symptoms are singularly absent. (8) That it is strangely resistant to local treatment. (9) That it consists histologically of a superficial inflammation affecting the subepidermal layer with dilatation of vessels, edema, and infiltration of cells; and an e-le-matous condition of the epidermis with more or less defect in the process of cornification. (10) That it may be regarded as belonging to a group of superficial inflammations of the corium, with secondary changes in the epidermis. [J. M. S.]

25.—In the management of eczema neither plain water nor soap must be used. It is safe to cleanse the part with rain water, with the juice of bran, starch or boiled oatmeal once every 24 hours. Immediate drying with a soft towel is recommended. The addition of a drachm of soda bicarbonate or bichlorate to the pint of fluid is useful if there is much exudation in the form of crust. Some antiseptic fluid may also be added with advantage. An important point is to ensure rest to the part. The sound parts of the skin should be washed daily with soap and water. The eczematous surface should always be protected by some application. Waldo does not think the kind of application is so important as the protection of the part. To a wet eczema it is often better to apply lotions, as in this way the local remedy is enabled to come into close contact with the living tissues. Internal treatment must not be ignored; the author recommends blue pill, aperients, quinine and benzo-naphthol. [J. M. S.]

1. Playfair discusses chronic invalidism in women. Its causes, and cure. He remarks that it was until com-

paratively lately that the group of morbid symptoms characteristic of this condition held a recognized place in textbooks, although it is common enough. The symptoms are altogether functional and therefore irregular, and have given rise to a great many terms, such as nervousness, hysteria, neurasthenia, and spinal irritation. Playfair believes that the best prophylaxis is to be found in the adage, "*Mens sana in corpore sano*." The thoroughly strong-bodied healthy girl very rarely lapse into the invalid woman. Overwork at school is a prominent factor in the production of the condition, and long before the symptoms of break-down become prominent nature throws out danger-signals such as amenorrhoea, menorrhagia, headaches, emaciation, and the like. The school-girl should have plenty of out-door exercise and should not worry. As to treatment, the rest-cure of Weir Mitchell probably gives the best result. The selection of a proper nurse is almost as important as that of a medical man. Suitable food, massage, frequent light feeding, the relief of constipation and physical and mental rest, together with change of air and scene constitute the most useful methods of treatment. [W. A. N. D.]

2.—Weber writes on the occurrence of green or blue urine and its most frequent cause. He states that it occasionally happens that individuals pass blue urine, who are unaware of having taken methylene blue or any other similar anilin dye. The author mentions that individuals are apparently well who pass green or blue urine without any obvious cause, but have, as a rule, indulged in sweets colored with methylene blue. A fact that bears emphasis is that the secretion of such green or blue urine generally occurs in children and young women who partake freely of sweets. He reports a number of instances which illustrate that sweets are often responsible for the secretion of blue or green urine. A number of characteristics by which blue or green urine may be recognized, when due to methylene blue, are mentioned. They are as follows: 1. When one decigram of methylene blue is ingested, the urine which is passed an hour or so afterwards, has a greenish tint. Later it becomes deeper green and finally blue. The color produced by the blue lasts three or four days. Occasionally on the 5th day, the greenish tint may still be noticed in the morning urine, while on the preceding day, the mid-day urine was not discolored. When sweets which contain methylene blue are taken at intervals during several weeks, it is not surprising to hear that only the morning urine was colored green. 2. The amount of methylene blue determines the color of the urine, varying from a faint greenish yellow to a deep blue. When such urine is placed upon white paper or blotting paper it is discolored blue. 3. Boiling sometimes intensifies the color of the urine for the reason that methylene blue is excreted as a colorless chromogen. The color will return when the urine is heated with acetic acid. 4. Filtering lessens the color of the urine. 5. A solution of caustic potash, without heating, decolorizes the urine. Boiling with strong nitric acid or hydrochloric acid also decolorizes, while cold nitric acid produces no effect upon the color. Chloroform has the property of taking up the dye when mixed with urine, and this substance rapidly becomes blue. Later, however, does not become colored. When chloroform is mixed with an aqueous solution of methylene blue, it gradually becomes mauve, and afterward purple or red. When blue or green urine is examined with a good spectroscope, sometimes absorption bands can be made out, identical with those yielded by the aqueous solution of methylene blue. Living bacteria have the property of reducing and decolorizing methylene blue in the urine. When the urine is undergoing decomposition the lower portion of the liquid owing to the action of the micro-organisms loses its color and only the upper portion retains it, because the latter is directly in contact with the oxygen of the air. After the liquid is shaken, thus mixing it with oxygen, the original color is regained. When this experiment is performed in a tightly corked bottle which does not contain oxygen, the blue color will not be regained. [F. J. K.]

3.—Smith and Taylor report two cases of black water fever. Case 1.—This occurred in a non-commissioned officer, who had been in Sierra Leone for over a year. During this period he had enjoyed good health, except that he had occasional attacks of fever. His illness began suddenly in the afternoon about three o'clock, when he experi-

enced shivering, vomited, and complained of pains in his back. Some hours later, he was passing bloody urine. Previous to his illness, he had been taking five grains of quinine three or four times a week. On the following day agonizing spells of vomiting were frequent and the urine still bloody. Within a few hours after the onset of the disease, jaundice showed itself, which became intensified as the disease progressed. Examination of the blood failed to detect any malarial parasites. The medicinal treatment consisted of boric acid and arsenic, and such symptomatic measures as were necessary. Intravenous injections of normal salt solution were given during the last four days of the illness with slight temporary good results. The fever persisted in spite of all treatment, and just before death the jaundice had almost disappeared. Hemorrhages occurred from the buccal, mucous membrane. The stools were scanty; they were bile stained. The fever never rose above 101° F., and with the occurrence of hemoglobinous urine the temperature dropped. On the tenth day death occurred. A number of blood examinations were made which revealed the following: On the second day of his illness, the red corpuscles numbered 1,900,000 and white corpuscles 10,000 per cubic millimetre; third day, red cells 1,700,000, white 10,000; fourth day, red cells, 1,000,000; fifth day, red cells 900,000; sixth day, 1,100,000 white cells 18,000; seventh day, red cells, 1,000,000; eighth day red cells 1,200,000 and white cells 10,000. At autopsy, marked fatty infiltration of the walls of the right ventricle was found; the heart muscle was soft and friable; fatty degeneration in the papillary muscles. The spleen was considerably enlarged, weighing nine ounces, its capsule was adherent to the surrounding structures. The pulp was much congested. A microscopical examination of films from the pulp showed that the splenic substance consisted largely of blood pigment and degenerated blood cells. The liver was enlarged, congested, and the seat of fatty degeneration. The kidneys were also much congested. The mucous membrane of the gastro-intestinal tract was congested; there were also present a number of submucous hemorrhages. Case 2.—This occurred in a West Indian negro soldier who presented symptoms similar to those described in the previous case, except that jaundice was not appreciable and hemoglobinuria was absent. Albumin was found in the urine in considerable amounts. An examination of the blood made on the third day of his illness revealed ring-shaped parasites in small numbers, but not at any other time in the course of the disease were malarial parasites found in the circulating blood. The temperature varied between 103.2° and 98° F. On the three succeeding days after the seventh day, the temperature was normal. It then rose slightly at intervals; just before death it reached 103° F., which was on the 11th day. Towards the close of the illness the patient had diarrhea. At autopsy, pathological changes were found similar to those described in the first case, except that the spleen was not enlarged, and that the femoral vein was the seat of thrombosis. Several abscesses were also found just beneath the splenic capsule; in the pus bacilli coli were present. [F. J. K.]

4.—This article is an abstract of the paper by Cash and Dunstan read before the Royal Society, June 20, 1899, on "the pharmacology of pyraconitine and methylbenzocaine considered in relation to their chemical constitution."

5.—Richmond reports a case of spontaneous gangrene which occurred in a female infant. The mother of this child was confined at full term on May 3, 1898. The labor pursued the natural course with only slight delay after delivery of the head. At birth, two areas of acute dusky inflammatory redness were observed on the child, one just below the occiput and the other over and around the seventh cervical vertebra. The upper inflammatory area sloughed. On the third day after birth the lower patch became gangrenous in its center. A black slough afterward separated. Later, internal strabismus developed, suggesting central cerebral disturbance, which was perhaps responsible for the superficial gangrene. There was no evidence or history of syphilis. The author believes that the lesions were trophic from central nerve mischief, and not caused by septic absorption. [F. J. K.]

6.—G. P. Newbolt reports a case of a girl five years of age who suffered from arrested growth in one limb. The author is uncertain whether this arrest of growth was due to a previous osteotomy for knock-knee, or wheth-

er it originated from rickets. He removed subperiosteally 1½ inches of the right femur with the most satisfactory results. Eight months after the operation the deformed limb had grown 1½ inches. [J. H. G.]

7.—F. G. Harvey describes the Roetter operation of laryngectomy. He thinks this operation has many advantages over the older method of doing a tracheotomy prior to the removal of the larynx. Three of the author's cases were operated upon in this way with very satisfactory results. In his other three cases a preliminary tracheotomy was done. [J. H. G.]

8.—Wm. R. Fox describes and illustrates a wire framework which he has constructed for the purpose of definitely localizing foreign bodies within the cranium by the X-rays. He suggests that this method, with some change in the framework, may be applied to other parts of the body.

[J. H. G.]

11.—Ord gives three points in practical midwifery, as follows: 1. The catheter in the course of a breech delivery is capable of saving life. 2. Hour-glass contraction of the uterus is avoidable. 3. Scoliosis is possibly caused by traction on the infant's body during birth, the rotation and traction together stretching the vertebral ligaments and thereby weakening the spinal column. In addition to this there is danger of injuring the suprarenal capsules during this process of traction. [W. A. N. D.]

MEDICAL RECORD.

October 5, 1901.

1. The Use of Linnations of the Elastic Ligature in Intestinal Surgery. THEODORE A. MCGRAW.
2. The Proper Method of Teaching the Anatomy of the Nervous System. L. HARRISON METTLER.
3. Pre-Medical Education. STANLEY COULTER.
4. The Chest Pantograph and the Manometer—Their Clinical Use and Value. C. B. VAN ZANT.
5. Pistol-Shot Wounds. THOMAS HAYES CURTIN.

1.—Theodore A. McGraw urges upon surgeons the use of his elastic ligature in intestinal anastomosis wherever possible. He points out the disadvantages and dangers of the Murphy button and the end-to-end anastomosis without the aid of mechanical means. He claims that in most instances the anastomosis can be made without these disadvantages and dangers if the elastic ligature be employed. It is the operation of gastroenterostomy that it is to be particularly preferred to other methods. It is said that in this operation and in the operation upon the intestines it is rare for peristalsis to be established within the first 48 hours, and that therefore the immediate establishment of an opening can have little advantage over that produced by the elastic ligature, which requires from two to three days. In many operations upon dogs the author has never found the ligature to fail to produce the separation of tissue about which it is placed. The claims for this method are that there is no incision of the bowel, no loss of blood, no escape of the feces, and no exposure of the peritoneum from bowel contents. The ligature must be firm, hard, perfectly round, and at least 2 mm. in diameter. It is said to be a great time saver where an enteroenterostomy is added to a gastroenterostomy. McGraw also claims that the elastic ligature will be found very useful in a division of cicatricial contraction of the intestine. After the ligature is tied, the peritoneal surfaces about it are brought together by Lembert sutures and by wrapping a portion of omentum about the anastomosis. [J. H. G.]

2.—L. H. Mettler presents a paper on the proper method of teaching the anatomy of the nervous system. He believes that this should be taught along its developmental lines. Studying the evolution of function and development of its constituent parts, which he holds enables the student to grasp the study more intelligently, and to retain it more tenaciously. [T. L. C.]

3.—Stanley Coulter discusses pre-medical education. During the course of this paper he describes the pre-medical course at Purdue University, which is arranged to meet a three-fold demand. 1. To furnish a broad and liberal education. 2. To give special and extended training in those subjects which underlie the strictly professional studies of the medical school. 3. By this correlation of work to shorten the time required to obtain the university and professional degrees. [T. L. C.]

4.—C. B. Van Zant describes the chest pantograph and the manometer, and gives their clinical uses and value.

The first instrument was devised by W. S. Hall, of Chicago, and while it was intended to fulfill physiological purposes, it is capable of considerable practical clinical utility, in estimating and recording certain diseased conditions. It enables clinicians to make and reduce tracings, which can be preserved and be a comparison of any progress of these features of our cases of pulmonary disease. This author thinks it is a definite means of keeping track of many conditions beside those of the thorax, and thus we may record the change in size and shape of the face in acromegaly, of the head in hydrocephalus, of the neck in goiter, etc. Van Zant also mentions the ordinary manometer for which he describes a new field of usefulness in the surgery of the chest. He mentions the elasticity of the lung parenchyma, and states that there is a constant tendency for the lung to pull away from the chest-wall, that is, a tendency to a separation of the pulmonary and costal layers of the pleura. Normally this cannot be accomplished, and leads to a constant condition of negative pressure, known as the intra-pleural or intra-thoracic pressure. If after connecting it with a manometer, you insert a small hollow needle carefully through the chest-wall, the moment it enters the pleural cavity the suction there leads to a movement of the mercury in the manometer towards the pleura. If, through disease, the layers of the pleura are adherent, the pleural cavity is thereby obliterated, and its negative pressure is annulled. Under these circumstances there will be no movement of the fluid toward the chest. Thus the manometer affords an easy and safe method of disclosing the presence or absence of pleural adhesions in any case. [T. L. C.]

5.—Thomas H. Curtin discusses the subject of **pistol-shot wounds from a purely medical standpoint**. In the examination of these cases, we should first look for the wound of entrance, and then for the wound of exit, if it exists, and determine the distance the pistol was held from the person when fired. Means are described for judging this, as well as for studying the penetrating power, and the important question of the caliber of the bullet. Methods of examination of the pistol from which it is to be determined whether the shot was fired, and the study of wounds made by blank cartridges, are included. [T. L. C.]

6. Acute Edema of the Uvula, Palate, Pharynx and Epiglottis, Following the Excessive Application of Adrenal Solution Preserved with Chloretone. SOLOMON SOLIS COHEN.

2.—W. W. Kerr, describing his treatment of acute rheumatism, says that rest in bed is an essential factor and should be maintained for at least ten days after the temperature has become normal and all other symptoms of the case have disappeared. Freedom from pain in the joints must not be taken as the indication for allowing any indulgence to the patient, because cardiac changes may arise after the joints have recovered; furthermore, myocardial changes may exist with very few symptoms until the muscle yields under imposed strain, and therefore the patient should be kept at rest so that both myocardium and endocardium may have ample opportunity to recover from any injury to their structure. Sodium salicylate is the remedy most frequently used in the treatment of rheumatism. It should be given in doses of twenty grains every two hours until the fever is reduced and the acute articular pain subsides; after this the intervals between the doses may be increased to four or six hours, and continued in this way for at least four weeks. If the drug be discontinued before this time, the patient is almost certain to suffer from a return of symptoms, and hence it has been said that acute rheumatism, like other fevers, is a self-limiting disease and that salicylates do not shorten its duration, but merely prevent its injurious effects upon the tissues. If the salicylates distress the stomach, depress the heart,

cause delirium or other nervous disturbances, or give rise to various skin eruptions, then salicin or salol may be substituted, if there is no renal disturbance. He also advises an alkali in addition, such as citrate of potash, twenty grains at a dose. Cardiac complication can be cut short by small blisters. As to diet, milk should be the chief food until the symptoms abate; then broths and farinaceous substances may be gradually added. Bland's pills are advised while there is anemia. [T. M. T.]

3.—W. S. Magill concludes his article as follows: Absolute purity is the only condition by which ethyl bromide can be admitted as an agent of almost perfect safety for the induction of anesthesia. The dangers of its cumulative dose and consequent restriction to short narcosis have been previously explained. For prolongation of unconsciousness, the narcosis induced by this drug is easily and safely continued with chloroform in very small quantity. A teaspoonful of chloroform (in drop doses) is frequently all that is needed to continue the ethyl bromide induced anesthesia for the space of an hour. [T. M. T.]

4.—L. Kolipinski recommends the use of lager beer in acute vomiting, and says that the beneficial effects are most marked in women and in those who are not habitual consumers of alcohol as a stimulant or intoxicant. Of the two varieties of beer—the pale and the dark—the latter is preferable. As to the quantity to be given, the amount need be but small, a bottle or two suffices. Singularly good results can be obtained from small doses. This is illustrated in the attacks of nausea, bilious vomiting, vertigo and sleeplessness, often a striking syndrome of epidemic influenza in women; a wine-glassful of beer, repeated in half an hour, will immediately soothe the disturbed organ and give a night of refreshing sleep. [T. M. T.]

5.—Byford remarks that it is very seldom necessary to remove the uterine adnexa for inflammatory disease. He believes that after the age of 30 years these organs have already served their function in stimulating individual development. After that age they are only of use to propagate the species, and, in functioning, act more or less as a drain upon the general system and tend to hasten senility. Women prefer as a rule to suffer with unhealthy organs rather than have them removed. He endeavors, therefore, to practice conservative gynecology and to preserve sufficient ovarian tissue for normal function in women under forty years of age even at the risk of their being obliged to undergo a subsequent castration. There are cases in which the conditions require the complete abolishment of the monthly hyperemia of the sexual organs. There are other cases in which separation of adhesions and suturing of the parts on the higher level may be all that is indicated. Again there are others in which the diseased portion of the ovaries must be excised, the tubes made pervious, and the patient left unaltered as far as her sexual functions are concerned. The septic cases of disease of the uterine appendages should not be treated in a conservative manner. [W. A. N. D.]

THE NEW YORK MEDICAL JOURNAL.

1. The Lane Lectures on the Social Aspects of Dermatology. MALCOLM MORRIS.
2. Laryngology and Its Place in Medical Education. HENRY L. SWAIN.
3. The Influence of Climate upon Nervous Diseases, considered from a Physiological Standpoint. F. SAVARY PEARCE.
4. Was the Epidemic that Raged in Athens, B. C. 430, Genuine Bubonic Plague? HENRY M. FISHER.
5. Acute Amygdalitis: Its Treatment by the Local Application of the Tincture of Iodine. SAMUEL FLOERSHEIM.
6. Review of a Few Cases of Wounds Caused by Bullets from Revolvers of Moderately Large Calibre. J. HOBART EGBERT.

3.—F. S. Pearce states that functional disorders are more particularly affected by climate. Organic diseases, it will no doubt be found, are especially influenced by meteorological conditions as yet not definitely known to the physician, but in each type, the gleanings of clinical facts at our command seem to place the said therapeutic climatic results as principally dependent on states of atmospheric pressure and the consequent nutritional improvement produced thereby. The great altitudes favor circulation of the blood in the periphery of the body, and

assist nutrition, both by aiding the absorption of nitrogen from the air at low barometric pressure, and also by producing a much more active circulation of the blood, and therefore of its proteids containing nitrogen received from food products of digestion, thus doubly fortifying nutrition in some cases; therefore, the trophic function may advance too rapidly by the patient's ascending great heights. So that a great altitude is not good for the neurasthenic, who must appropriate nutriment slowly on account of the weakened central nervous system. Insomnia is benefited by lesser altitudes, while chorea, hysteria, and most of the functional maladies, are likewise favored by a sojourn at the sea level, provided other meteorological conditions are good, such as equable temperature, heat, and the non-prevalence of atmospheric moisture. Melancholia and depressive diseases are helped by high winds and moderate heat, to aid in general, bodily metabolism. In organic disease depending upon central or peripheral lesion, perverted function, as pain and sluggish circulation, will be helped by altitude; a greater altitude being desirable for diseases of the central nervous system, a lesser altitude being the desideratum in the cases of peripheral diseases, as in neuritis and vasomotor palsies, exemplified in Raynaud's disease, exophthalmic goitre, and allied affections.

[T. M. T.]

4.—In H. M. Fisher's article, the author tries to show that the epidemic that raged in Athens, B. C. 430, was true Bubonic plague, and says: (1) As to its origin. Thucydides tells us that it was rumored that it came from Ethiopia, beyond Egypt, and it is, the author thinks, reasonable to suppose that Southern Arabia may have been meant. This part of the world has been known from time immemorial to have been one of the chief breeding-places of the plague; (2) As to mode of propagation. Common rumor had it that the Peloponnesians had poisoned the cisterns of rain water used for drinking purposes in the Piræus; (3) In Thucydides' brief description of the disease, as he had observed it, he calls attention to the lividity of the hue of the skin covered with small pustules and ulcers; (4) The few patients who survived often, developed, during convalescence, gangrene of the fingers and toes and of the external genitals, and often became blind; (5) The disease was transmitted to the lower animals. Thucydides remarks that birds and beasts of prey that fed upon the many unburied bodies of the victims of the epidemic invariably died very soon. [T. M. T.]

5.—S. Floersheim concludes his article as follows: (1) The tincture of iodine is the most powerful antiphlogistic in inflammations of the throat; (2) Its action is very rapid, relief being often experienced within five minutes; (3) It has relieved the intense inflammation completely when all other remedies had absolutely failed to benefit; (4) Its use in sixty-eight cases of acute amygdalitis has been followed by marked benefit in every case; (5) The method of application is simple. [T. M. T.]

3. Association of Anemia with Chronic Enlargement of the Spleen. ARTHUR H. WENTWORTH.
4. Infantile Scurvy. EDWARD L. PEIRSON.
5. Rachitis. ARTHUR R. CRANDELL.

1.—Thomas reports the case of a man, 39 years old, who was attacked by a severe pain between the shoulders which confined him to the bed for 4 or 5 days. Since that time he had more or less pain in the back, but had been about. He noticed a slight uncertainty in the use of his legs. Once, on stooping to pick up something, he fell upon the floor. This uncertainty was no more noticeable in the dark than in the light. The feet had felt numb, and there was a sensation as of something tight about the abdomen. There was no ataxia. All the reflexes were normal except the desire to micturate had come on, and there was occasional difficulty in starting the stream. He had also noticed a slight lessening of the sexual desire, but no loss of power. There had been no dizziness and no headache. There was no ataxia. All the reflexes were normal except the skin reflexes. A diagnosis was made of pressure upon the spinal cord, probably from tumor in the upper dorsal

region, and a plaster-of-Paris jacket, massage, and a vigorous treatment by antisyphilitic medicines were advised. Later, the gait became slightly ataxic, Romberg's symptom was present, and there was slight incoordination in the movements of the legs, though this was not present in the arms. Still later, marked general paresis of the legs developed. The knee jerks were increased and equal; there was a slight patellar clonus and ankle clonus on both sides. The sense of pain and temperature were absent, and that of touch diminished to the level of the sixth rib. The urine which had previously been normal was found to contain albumin and albumose. An operation was advised, and as much growth as could be curetted out was removed. After the operation the patient developed a complete paraplegia with retention of urine, but this gradually improved, and the wound healed well. Under treatment by bone marrow and injections of Coley's toxins cure was effected. The tumor was a myeloma. [J. M. S.]

2.—Just as in acute disease the application of those agencies which maintain a healthy condition of the organism may be utilized to advantage when the latter is attacked by disease, so may we in chronic maladies obtain better results from the systematic application of the so-called hygienic agencies. Of these agencies water is probably the most effective. Phthisis affords the most striking illustration of the advantages of the hygienic treatment. Baruch attributes the favorable results to the irritant effect of cold water upon the sensory terminals in the skin which arouses the central nervous system to reflex effect upon the respiration, deepening it; upon the heart, improving the pulse, enhancing glandular action and excretion; upon the stomach, improving appetite, digestion and hematosis. Neurasthenia has proved very amenable to hydropathic treatment. Home treatment should be begun by allowing the patient to stand in water at 100°, covering the ankles, and washing him rapidly with a large piece of gauze dripping with water at 80°. This temperature is to be daily reduced 1° until 60° are reached. Diabetes, nervous dyspepsia, hysteria, sciatica, neuritis, lumbago, asthma and angina pectoris may be benefited by hydrotherapy.

[J. M. S.]

3.—Will be abstracted when finished.

4.—Pain is the first symptom that we notice when called to see a child with scurvy. The pain is first felt in the legs, then in the back and the arms. Next, swellings appear, and later the gums become spongy and ulcerated. There is no fever as a rule, and the tender swellings are not hot. The most common error is to call the cases rheumatism, yet rheumatism, Peirson believes, is extremely rare under 2 years, especially in the first 6 to 12 months of life, when these cases of scurvy appear. Rachitis, Pott's disease, acute anterior poliomyelitis, purpura and syphilis have been mistaken for infantile scurvy. Treatment consists of modified, uncooked milk with orange or lemon juice, fresh beef juice and iron. [J. M. S.]

5.—Rachitis results from chronic malnutrition, often reinforced by poor hygiene and unsanitary environment. Rachitic children are usually fat and may appear, at first glance, to be well developed. The muscles, however, are weak and flabby, and their action is enfeebled. Another very noticeable characteristic, the enlarged abdomen, or "pot belly," is due to weakness of the abdominal muscles, the condition being accentuated by the flaring of the lower costal margin and the atony of the muscular coats of the intestine, which results in distension of the bowels. Weakness of the back muscles produces a rounded kyphosis. Weakness of the muscles of the extremities may be great enough to stimulate paralysis. The ligaments show evidence of impaired nutrition in an undue laxity, especially in the lower extremities, resulting in hyperextension of the knee-joints, weak ankles and flat foot. Prophylaxis is the most efficient treatment; this includes painstaking and accurate feeding, careful hygiene and supervision of the methods of living. If prophylaxis has been neglected, active treatment should be instituted. A proper percentage of fats and proteids must be supplied, and improper elements in the diet must be eliminated. There is no specific for the cure of the disease. It is sometimes expedient to administer fat as cod-liver oil in assimilable doses. The anemia is said to be treated by the use of iron. Deformities may be prevented if creeping, walking and sitting up are restricted until the bones begin to harden. [J. M. S.]

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

8. Notes on One Hundred and Fifty Cases of Smallpox in Private Practice. ALBERT SOILAND.
9. A Satisfactory Operation for Certain Cases of Retroversion of the Uterus. J. CLARENCE WEBSTER.

1.—Vaughan classifies cirrhosis of the liver into the atrophic, hypertrophic, and mixed varieties. He gives the etiology, symptomatology, and pathology of these forms. In summarizing a comparison of the two diseases, he mentions the following which we quote in substance: "Atrophic cirrhosis is sometimes designated as the cirrhosis of Laennec and the hypertrophic disease as the cirrhosis of Hanot. The former is known as atrophic cirrhosis because from its earliest possible recognition the liver is less than normal in size; while hypertrophic is known as such because at every stage of the disease the liver is larger than normal. The atrophic is known as venous cirrhosis because of the early and constant involvement of the intra-hepatic branches of the portal vein; the hypertrophic is known as biliary cirrhosis because early appearance and constancy of icterus. The former might be known as toxic, and the latter as infectious cirrhosis. In the atrophic disease, ascites is an early manifestation and is often marked; in the hypertrophic, ascites is frequently absent and is never great. In the atrophic, icterus appears late, if at all; in the hypertrophic it appears early and is constant. Finally, in atrophic cirrhosis the primary destructive changes are in the hepatic cells; in hypertrophic cirrhosis the epithelium of the gall ducts is the site of the primary involvement." [F. J. K.]

2.—Musser outlines the treatment of cirrhosis of the liver when dealing with portal obstruction, ascites and biliary obstruction. In dealing with the first condition (portal obstruction) he does not deem it necessary to outline the treatment for its relief to practical and scientific men. He believes calomel is of great value in the treatment of ascites. Another drug which has proved serviceable in reducing ascites is apocynum cannabinum, in doses of fifteen, twenty or thirty drops, four times daily. When medication is without avail, tapping should be resorted to early. Musser has seen ascites cured after the hundred and fiftieth tapping. He calls attention to the necessity of surgical relief in cases of obstruction of the biliary passages with cholangitis and cholecystitis. [F. J. K.]

3.—Greene reports a case of acromegaly with enormous enlargement of the hands, wrists, feet, and ankles, which occurred in a man 25 years of age. Thyroid treatment was employed with the result that marked amelioration of the symptoms followed. [F. J. K.]

4.—In his paper on the increasing sterility of American women, Engelmann bases his investigation upon 1700 cases in private and dispensary practice in St. Louis; 1146 American born, 357 Irish and Germans, 197 negroes. In addition there are 2038 women taken from the gynecological records of Massachusetts. The results obtained indicate that at the present time 20% and over of married women are childless, whilst in the preceding centuries, in the earlier days of the country, only 2% were sterile; and when we compare these figures with the generally accepted rate of sterility, 11%, found by Simpson, and so generally accepted as to be called "Simpson's law," the difference is so great that it would appear that proof is needed before these facts can be accepted. An examination of the gynecological writings, however, of this country and elsewhere show that the figures are correct. By sterility Engelmann understands the condition of the woman who is married three years without giving birth to a

full-term child; by absolute sterility he means a woman who has never conceived; by relative sterility he means that she has conceived and miscarried. Greater luxury and wealth invariably go hand in hand with higher sterility. The number of the absolutely sterile is greater than that of the relatively sterile. That is, the number of those who have never conceived, natural or artificial causes preventing, is greater than that of those who have borne no full-term child, but admit of having miscarried one or more times. In this country this group of relatively sterile is over 8% of all married women. In his dispensary practice the absolutely sterile were 11.6% and the relatively sterile were 3.8%. The absolutely sterile he finds to be about 12% among Americans. The sterility is highest among college graduates, 33%. [W. A. N. D.]

5.—Deever and Ross analyze 268 operations for appendicitis performed at the German Hospital during the year 1900, and devote considerable time to the discussion of the mortality of appendicitis. 144 of these cases were operated upon during an acute attack and 26, or 17.8 per cent., died either from the disease or some inter-current trouble. One patient died of diabetes, another had advanced phthisis, and a third died of a postoperative pneumonia. If these three are eliminated the mortality is reduced to 15.9 per cent. for acute appendicitis. Seven of the 26 fatal cases had a general purulent peritonitis at the time of operation and in 7 others this condition followed operation. Septicemia was the cause of death in 8 cases. Secondary collections of pus were met with 11 times; 7 times in the pelvis, 3 times in the post-cecal region, once to the left of the appendix region, and once in the abdominal wall. Gangrene of the cecum and colon was encountered 7 times; 5 times it was met with at the time of operation and twice it developed subsequently. The most common cause of death in cases not submitted to operation is septic peritonitis. Obstruction of the bowel is also a frequent cause of death in these cases. Occasionally septic material is deposited in distant organs, such as the liver, brain, heart, etc. Occasionally an abscess will rupture into the bladder, producing a fatal cystitis or pyelitis. In cases of chronic appendicitis where no adhesions are present, or in acute appendicitis where the disease has not extended beyond the peritoneal coat, the mortality should not be below that of any aseptic abdominal operation. The presence of adhesions adds considerably to the mortality rate. Of 124 cases, which included all the chronic cases and those acute cases in which the inflammation had not extended beyond the peritoneal coat, there was but one death. Particular attention is called to the rapidity with which the disease progresses in some cases. The authors do not think it is possible for a patient to recover from a general purulent peritonitis. Cases of this nature reported in literature the authors think are cases of extensive but not general peritonitis. Stress is laid upon the necessity of evacuating and draining all pus pockets. Excepting in a few instances it is thought that the appendix should be removed in all pus cases. Necrosis of the bowel probably due to septic emboli in the veins of the mesentery, metastatic abscesses, septic endocarditis, and obstruction of the bowel, account for the death in many of the acute cases. Of the 118 acute cases which recovered after operation, in 61 pus was present. In 21 of these 61 the appendix was perforated and gangrenous. Fecal fistulae occurred six times; four closed spontaneously and two required operation. During the year 1900 there were 11 cases of appendicitis at the German Hospital which were not operated upon. Three of these died and five left the hospital with a mass in the right iliac fossa. It has been the authors' experience that appendicitis increases in severity with each attack. The authors next discuss the diseases complicating appendicitis, among which are diabetes, nephritis, septic pneumonia, etc. In phthisical cases operation is advised only as a last resource. Appendicitis due to typhoid bacillus is thought to be much more common than is generally believed and the fever is no contra-indication to surgical treatment. Delay is said to be a greater causative factor in the mortality of appendicitis than any of the complications of the disease. Deever has not found the subarachnoid infection of cocain of advantage in operations for appendicitis. [J. H. G.]

6.—Pearce discusses the symptomatology of cerebral hemorrhage and reports two cases which included the necropsy findings. [F. J. K.]

8.—Solland relates his experience with 150 cases of small-pox which came under his observation during the past twelve months. The cases occurred principally among negroes in Central Louisiana. The course of the disease was typical, except in that secondary fever was not well marked in most of the cases. In 34 instances the disease was of the confluent variety. There was only a single death in this series which the author states occurred in a mulatto, 25 years of age, who had suffered from the hemorrhagic type of the disease. [F. J. K.]

9.—Webster describes a new operation for retroversion of the uterus as follows: The patient being in the Trendelenburg position, the abdomen is opened, adhesions are separated and other pathological conditions which may be present attended to. The fundus of the uterus is elevated and pushed forward. A small hole is then made through the broad ligaments on one side under the utero-ovarian ligament near the uterus. Through it a pair of forceps is passed from behind in order to grasp the round ligament about an inch from its uterine end. The latter is then pulled through the broad ligament in a double fold. It is carried across the back of the uterus a short distance above the utero-sacral ligaments and is then stitched in this position with chromic cat-gut. A similar procedure is carried out on the other side, the second round ligament being stitched to the back of the uterus above or below the first one or crossing it. The amount of overlapping of the round ligaments depends upon their length or laxity. Each ligament is also stitched to the edge of the hole in the broad ligament. As a result the round ligaments are much shortened and act both in elevating the uterus as a whole and preventing it from returning to its retroverted position. [W. A. N. D.]

5. The Efficacy of Quarantine and Fumigation in the Prevention of the Spread of Yellow Fever Without Molesting the Mosquito. JOSEPH WALDAUER.
6. On the Agency of Parasitic Vermin and Other Insect Pests in the Spread of Disease. GEORGE HOMAN.
7. The Lane Lectures on the Special Aspects of Dermatology. IV. MALCOLM MORRIS.

1.—W. P. Manton reports a case of villous cancer of the gallbladder with secondary invasion of the liver, duodenum and surrounding structures. The patient was a woman of 58 years. She was operated upon for gall stones and died nine hours after the operation. A case is also reported of cancer of the bile-ducts with probable invasion of the gallbladder presenting symptoms resembling gall stones, in which cholecystomy was performed, and the patient died on the third day. The third case presented is that of primary cancer of the hepatic duct and fibrous occlusion of the cystic duct. Although primary cancer of the gallbladder and bile-ducts is rare, recent investigations go to show that it is not so uncommon as generally supposed. [T. L. C.]

2.—F. Forchheimer discusses the influence of heredity on appendicitis. For twelve years his attention has been called to appendicitis in families, and the results of these observations form the basis of this paper. He summarizes the history of a family of 25 members, five of whom have had appendicitis, of which four were relapsing and one was operated upon after the first attack. Of the four with relapsing form, only one has been operated upon; the other three have been free from relapses 3, 7, and 11 years respectively. There was no mortality. The second group, 17% of the whole family of 52 members and three generations, had appendicitis, of which one case was fatal, one suppurative, 6 mild and 6 relapsing. His third table is of a New England family whose medical history is given. In this whole family there have been 7 cases of appendicitis out of 22 members—33%—1 purulent, 2 of the ordinary type ending in resolution, and 4 relapsing cases. [T. L. C.]

3.—G. Hudson Makuen presents a paper on cleft palate

and its relation to speech. The various defects of the palate which interfere with speech are (1) Perforations. (2) A lack of union between the lateral halves, commonly known as a "cleft." (3) Paralysis of the muscles. Makuen emphasizes the importance of a few minor surgical procedures for the purpose of increasing the available size of the velum and giving it greater freedom of action. Briefly they are follows: (1) Separating the adhesions that often exist between the pillars of the palate on either side, and the remnant of tonsils. (2) Forceful stretching of the velum with the finger after the division of some of the tense fibres of the palato-glossi and the palato-pharyngeal muscles. (3) Training and developing the velum palati muscles by means of both direct and indirect voluntary exercises. [T. L. C.]

4.—J. A. Scott reports a case of endocarditis developing during typhoid fever. A soft systolic murmur at the apex, with a slight increase in size of the left ventricle was discovered on the 27th day of the disease. The patient made a good recovery. [T. L. C.]

5.—Joseph Waldauer gives his personal experience with the efficacy of quarantine and fumigation in the prevention of the spread of yellow fever without molesting the mosquito. He describes the quarantine at Clinton, Miss., in 1897 and of McHenry, Miss., in June, 1898. He concludes by asking that rational quarantine be maintained to avoid a spread of the disease. [T. L. C.]

6.—George Homan presents a paper on the agency of parasitic vermin and other insect pests in the spread of disease. The paper discusses, in a general way, the culpability of the mosquito, gnat, the horse-fly, the cattle-lick, the flea and the bed bug in the transmission of disease. [T. L. C.]

CENTRALBLATT FUER INNERE MEDIZIN.

July 6, 1901.

The Technique of Demonstrating the Presence of Peptone in the Urine and Feces. O. FREUND.

The test recommended is as follows: 10 c. c. of urine are acidulated with 2 or 3 drops of 20% acetic acid, 5 c. c. of 20% lead subacetate solution (or lead acetate) are added, well boiled and filtered. Potassium hydrate solution is added to the filtrate as long as it produces a precipitate, it is then boiled momentarily and filtered. The biuret test is then applied—directly with weak copper sulphate solution, as the mixture is already alkaline. The test is said to have the advantage of excluding any error due to urobilin, uroerythrin, urocasein bile-pigments or hematorporphyrin; the fluid to be tested is practically colorless. The test is used in the same way with feces; a series of tests with normal feces showed the constant absence of substances (albumoses) giving this test. [D. L. E.]

July 13, 1901.

Indicanuria, Oxaluria and Diabetes.

W. v. MORACZEWSKI.

Moraczewski's article is merely a suggestion that, since indicanuria is common in both oxaluria and diabetes, and since these two affections are not uncommonly present coincidentally and seem to have some relation to each other, the indicanuria in diabetes may be the expression of an oxalic acid poisoning in this disease. He believes that oxalic acid poisoning is the primary condition and that this may produce the evidences of acid intoxication seen in diabetes. His idea that oxalic acid poisoning produces the indicanuria is based largely upon the fact that Elsa von der Leyde has found that indicanuria occurs after experimental intoxication of animals with oxalic acid. [D. L. E.]

Typhoid Fever in an Esquimaux, With Positive Widal Reaction.—Cochez reports a case of typhoid fever in an Esquimaux aged 23 years, who died with perforation after laparotomy, in Algeria, on the nineteenth day of the disease. There was a marked serum reaction, with a dilution of 1 to 500. The brain weighed 1370 gm., the spleen only 65 gm. The liver showed a striking amount of sclerosis for so young a man. The diagnosis was difficult. It seems possible that, had surgical relief come sooner, instead of three days after perforation, he might have recovered. (*Bulletin et Memoires de la Societe Medicale des Hopitaux de Paris*, 1901, No. 10). [M. O.]

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fiftieth Annual Meeting Held at Philadelphia, September 24-25, 26th, 1901.

Continued from Page 557.

Reforms in Medical Education, by Dr. H. M. Shallenberger, of Rochester. The author claims that the education of medical students is of a lower grade than in other sciences, and that commercialism in medical colleges is responsible for the many failures. The number of graduates is in excess of the number needed, namely, one physician to eight hundred inhabitants, although even if allowance is made for the increased number of physicians, there is room for them if suitably prepared. The paper was discussed by Dr. E. B. Borland, of Pittsburg, Dr. Bates, of Scranton, and Dr. Beates, of Philadelphia.

The Duration of Immunity from Diphtheria Antitoxin, by Dr. Henry D. Jump, of Philadelphia. The experiments upon animals that were made to determine the duration of immunization show that in goats a maximum antitoxicity was obtained on the fourth day. The literature on the subject was freely consulted and the profession warned against insufficient dosage and delay. The author stated that in his private practice he inoculates every child exposed to diphtheric infection with 500 units of antitoxin, and claims brilliant results thereby.

The Vermiform Appendix, by Dr. Edmond W. Holmes, of Philadelphia. The author's observations were based upon an examination of 110 appendices. He divides the anatomy of the appendix into four subdivisions. The author showed an interesting number of specimens varying from one and one-quarter to seven inches in length. Dr. Holmes explains that therefore the size of the appendix has no relation to the size of the viscera or to the stature of the individual. A seven inch appendix may extend to the left and give rise to pain on the left side. In touching upon the surgery of the appendix, the speaker believes that frequently in searching for it, the edge of the psoas muscle is palpated. The paper was discussed by Dr. J. B. Roberts, of Philadelphia, who expressed his admiration of the specimens and of Dr. Holmes' paper.

The Doctor's Fee—Is it Fixed and Definite? by Louis J. Lautenbach, of Philadelphia. This paper dwelt upon the size of the fees obtained in other professions, and the utter disproportion between them and those received by physicians.

Therapeutic Notes, by Dr. Minnaeus Fussel, of Media, Pa. The speaker related his favorable results with a tincture of the chloride of iron in rheumatism, which, however, proves refractory to the remedy if in the acute stage. In epidemic dysentery he has employed large doses of ipecac with excellent results combined with a mustard plaster to the epigastrium. In addition there was discussed bichloride of mercury in rhus poisoning, and the use of mercurial ointment in pruritis.

Before the next paper was read delegates from the Pharmaceutical Association were presented and welcomed.

Bronchial Affections in Gout and Obesity, by Dr. J. M. Anders, of Philadelphia. Although the pathogenesis of the abnormal conditions in the lungs in obesity is not clear, it can be assumed that the deposit of fat in the body plays a mechanical part. He describes the symptoms concurrent with overfatness, namely pain in the subscapular and intra scapular muscles, more marked when the patients make an effort to maintain the erect posture. The physical signs vary, but as a rule tactile fremitus and percussion notes are enfeebled on account of the abnormal deposition of fat. There is a weakened vesicular murmur, although in rare instances the murmur may be exaggerated. Among the adventitious sounds are moist rales, although the author has also observed whistling sounds, the presence of mucus, however, predominating on auscultation. The author discussed asthma in obese subjects and the theories of its cardiac origin. Asthma in corpulency is due to the high position of the diaphragm in individuals who overfeed.

There is good reason to believe that hepatic inadequacy may be a cause. He believes that the severe paroxysmal dyspnea in asthma can be helped by assuming the erect posture, as there is no characteristic sputum or vaso motor spasm in these conditions. The question of the relation of asthma to polysarcia is somewhat obscure, the author's conclusions being (1) that asthma occurs in about 5% of the cases of obesity; (2) that it only occurs in extreme polysarcia; (3) that there is present a gouty state or history in most cases in which true asthma is secondary to the obesity; and (4) that about one-half of the cases are curable by overcoming the causative condition. (This paper will appear later in the Philadelphia Medical Journal).

Pseudo-Leukemia with Enlargement of the Liver and Spleen Due to Lymphatic Tuberculosis. By Dr. Joseph Sailer, of Philadelphia. Dr. Sailer discussed the forms of pseudo-leukemia, in which the etiology is tuberculosis of the lymphatic structures, and reported three cases of this condition, all of which were confirmed by autopsy. The peculiar features of the disease are moderate anemia, no leukocytosis, enlargement of the liver and spleen, the former being usually tender. Anasarca with terminal ascites and an extremely irregular temperature curve are additional features. In some cases there are sterile tumors springing from the thorax, and a terminal military tuberculosis of the lungs is a frequent feature. The pathological changes are enlargement of the lymph glands that often fail to show cheesy areas, but contain tubercle bacilli. There is subacute tuberculosis of the liver and spleen and occasionally a large fibrous tumor of the mediastinum. He called attention to the important paper of M. Sternburg on this subject, and to the various articles by Askanazy, Claessen, Brentano and Tangle.

The afternoon program terminated with a lawn party given to the Society by the Provost, Trustees and Faculty of Medicine of the University of Pennsylvania, the guests and visiting ladies of the Society being included. The lawn party was given at Houston Hall on the University campus. During the evening receptions were given to the members of the Society, guests and visiting ladies, at Jefferson Medical College, and at the residence of Dr. James Tyson, and Dr. J. V. Shoemaker, Governor Stone and staff in uniform also attending.

THIRD DAY—MORNING SESSION.

The session was called to order at 9.30 A. M. Resolutions were adopted advocating the existence of a psychological laboratory in the Department of the Interior. Resolutions were also adopted advocating vaccination for the prevention of smallpox, believing that it is harmless to the person that is vaccinated, and endorsing compulsory vaccination of school children. The treasurer's report followed. Governor Stone, of Pennsylvania, was next introduced and welcomed. In his reply the Governor made an address which was full of both humor and eloquence. He stated that he always believed that there was more politics in the average doctor than in any other individual. His condemnation of Christian Scientists was vociferously applauded. The Committee of Enforcement of State Medical Laws reported progress. The scientific program of the morning was then begun.

Address in Surgery, by Dr. James W. MacFarlane, of Pittsburg. The author of this address expressed his gratification for addressing the society in Philadelphia, where there had always existed a galaxy of physicians and surgeons of international reputation. His paper was devoted to the arrest of hemorrhage by torsion. He considered torsion first as limited and second as free torsion, the latter being employed as a rule. There is no advantage in limited torsion, as it consumes time and requires two forceps instead of one. He showed a diagram illustrating the method of free torsion. In his experience, if free torsion failed, a ligature is required or compression, and not limited torsion. Torsion has been assigned by many surgeons to a place second to that of the ligature. As a question of time, torsion is superior to the ligature, there is no foreign body of the wound, and not at all of the profession has trained assistants or nurses at their disposal. He has observed that in cases of railroad accidents where limbs have been torn from the body that hemorrhage has been perceptibly arrested by the torsion produced by the car

wheels. The procedure is available both in large and small vessels, atheroma of arteries being no contraindication to its employment.

The Operative Treatment of Bladder Descent and Sacculization. By Dr. George Erety Shoemaker, of Philadelphia. The author discussed the etiology of the various displacements, and in discussing downward displacement stated that it may occur in association with prolapse of the uterus, although it may even be present with the uterus in situ. Suprapubic operations have little immediate or no permanent effect on the bladder position unless supplemented by other methods. The author's method of operative interference comprises several operations. These operations may be done at one sitting if the patient is in the proper condition to undergo them, and if he or she can stand ether for one hour and a half. These operations consist in, curettement of the uterus, amputation of the hypertrophied cervix, attaching the vagina higher to the uterus, taking in all slack tissue, carefully repairing the perineum, taking care to pick up the fascia, and then opening the abdomen and suspending the uterus.

The Present Status of the Bottini Operation as a Means of Treatment in Cases of Obstructing Senile Prostatic Hypertrophy. By Dr. Orville Horwitz, of Philadelphia, whose conclusions are as follows:

1st.—There is less fear on the part of the patient to submit to the Bottini operation than there is to any other surgical procedure so far suggested for the relief of prostatic hypertrophy.

2nd.—The principal advantages to be derived from the method of treatment are: Only a short period of time is required in order to perform the operation; which is attended with but little shock and usually but slight loss of blood; convalescence is rapid and the mortality is lower than that of any other radical measure. Cures are produced in the large majority of cases, especially if the operation is undertaken early. Marked improvement may be looked for in a vast number of cases that otherwise would be condemned to suffer, as the danger attending any of the other radical methods of treatment would be too great to warrant their being employed.

4th.—Failures occur in but a comparatively small percentage of cases; want of success being due to the pathological changes and complications which have taken place. Especially is this true in those instances in which an incurable cystitis exists.

5th.—The operation is contraindicated where a valve-like formation exists; or where there is a greatly increased overgrowth of the three lobes, associated with tumor formation, giving rise to a pouch, above and below the neck of the bladder.

6th.—It may be employed with benefit, and safely, as a palliative measure in cases of prostatic hypertrophy of long standing associated with cystitis, when the general health will be improved, and constipation, which is usually associated with the condition, relieved, mitigating the prostatic spasm of the urethra; and rendering the insertion of the catheter easy and painless.

7th.—Pyelitis, when present, adds greatly to the danger of the operation, but is not a contraindication to its employment.

8th.—The character of the growth has but little bearing on the result of the operation.

9th.—The operation may be employed as a safe and satisfactory means of causing suprapubic fistula to close which is so frequently associated with hypertrophy of the prostate gland.

10th.—In suitable cases it is not only the best radical measure so far devised for the relief of prostatic hypertrophy, but is attended by the smallest mortality.

11th.—The operation is especially indicated in the beginning of obstructive symptoms due to hypertrophy of the prostate gland, and may be regarded as a prophylactic method of treatment.

12th.—The operation is capable of producing a symptomatic cure in a great number of cases of various conditions and configurations of the prostate gland due to hypertrophy, as is shown by the disappearance of prostatic spasm, the restoration of the function of the bladder to its normal condition, and the improvement of general health.

13th.—In operating early, before the prostate has become much enlarged, the safest method to pursue is to perform a preliminary perineal cystotomy, introducing the "peri-

neal galvano-cautery incisor" of Chetwood, so as to make the incision in the prostate.

14th.—In some cases a prolonged preparatory treatment is necessary before the operation can be safely undertaken.

15th.—In cases of prostatic obstruction, which have existed for a lengthened period, where there is chronic cystitis, the physical condition of the patient being below par, both local and constitutional treatment must be persisted in for months after the operation before the great benefit derived from the procedure can be insured, which treatment would be ineffectual unless the obstruction had first been removed. This paper will be published in the Philadelphia Medical Journal.

The paper by Dr. William N. Beach, of Pittsburg, on **Tuberculosis of the Rectum**, and that of Dr. S. Birdsall, of Susquehanna, Pa., on **"Some Practical Points in the Treatment of Typhoid Fever,"** were read by title.

Rare Complications of Appendicitis with Their Treatment. By Dr. Earnest Laplace, of Philadelphia. Dr. La Place stated that if appendicitis was due simply to an unmixt infection, a pathological picture could be drawn and we would recognize in appendicitis a disease of definite incubation and duration, with a crisis and resolution as in the case of pneumonia. But as we know the disease it is from the first a mixed infection with one or the other microorganisms predominating, depending upon the soil afforded by the patient. The extremes are its mildness in one case, to gangrene within 24 hours in other cases. Pain is not only produced by adhesions preventing peristalsis, but also by irritation of the toxins. In cases of a chronic course, abscesses may result which give vent to their contents in places of least resistance, too numerous to mention. The author quoted a case of empyema due to appendicitis on account of the sinus, which had communicated with the thorax. Examination showed that the caecum and ileum had been tied down to the pelvis by dense adhesions which enclosed foul pus, the latter communicating with the thorax. The second case reported was that of a male 26 years of age, who was operated on for chronic appendicitis, and who had an abscess in the right iliac region which had burrowed its way through to the retro-peritoneal region, and had perforated the ureter. The third case was that of a male with pain in the right hypochondriac and iliac regions, and in whom the abscess had burrowed its way upward, finally producing a cholecystitis. Both the urinary bladder and the rectum have been invaded, and in a case where pus had been persistently passed in the urine a probe showed that the abscess had found its way to the bladder. Fever may be absent. Dr. Laplace calls attention that in every case there was a time, had operation been performed, the patient would have been cured. The paper was discussed by Dr. Joseph Price, of Philadelphia, Dr. Adolph Koenig, of Pittsburg, and Dr. Mordecai Price, of Philadelphia, and closed by Dr. La Place.

Radical Cure of Hernia. By Dr. Edmund W. Holmes, of Philadelphia. The author describes the mechanism of hernial descent. He stated that one ought not to put too much emphasis on strengthening the ring or drawing down the rectus abdominis, but that the old ring should be obliterated, as well as the canal, and a new one created in a state of obliquity similar to that in nature. The surgical world still awaits the ideal operation for the radical cure of hernia.

A Case of Perforating Typhoid Ulcer; Laparotomy; Recovery by Dr. Wm. L. Rodman, of Philadelphia. The report of a case of enteric fever in a child aged twelve years, in which perforation occurred after all medication had been tried. There were marked nervous symptoms, at first some abdominal pain and a twenty minute chill. Digitalis, strychnine, nitroglycerine, strophanthus, alcohol and hydrotherapeutic measures to combat the fever had been employed. The abdomen became distended and stupor was employed. Continued vomiting ensued and peritonitis became marked. When Dr. Rodman saw the case he concurred on the diagnosis of appendicitis and found an enormous tympany. As a last resort operation was advised and a four inch incision made in the median line, and the perforation found almost underneath the incision.

(To be continued.)

TWENTY-NINTH ANNUAL SESSION OF THE AMERICAN HEALTH ASSOCIATION.

Continued from Page 558.

Dr. Gorgas believed that with the total extermination of the mosquito there would be no yellow fever. For the destruction of the new-born *stegomyia fasciata* oil has been placed on the surface of standing water, with good results. The yellow fever patients in the hospitals are protected by mosquito-bars, thus isolating them from this insect-contamination.

Dr. Formento, while supporting the theory that the mosquito does carry yellow fever, did not think that that was the only method of infection; it would be very fortunate if it were and would greatly simplify the problem; we should not all at once throw away as worthless the experiments of centuries. He cited several cases of infection by fomites.

Dr. Wasdin asked whether we should go back and displace all of our known methods of quarantine. New Orleans has been kept absolutely free from yellow fever invasion by methods to prevent that disease other than any attempt to kill mosquitoes. While he believed that the mosquito was the medium of yellow fever infection, he thought there were likewise other media.

Dr. M. J. Rosenau reported a case of a mosquito living 13 days in a trunk en route from Neuville to New York (which fact was subsequently combated by Dr. Reed on the basis of "false observations"). Dr. Rosenau had, by repeated experiments, kept mosquitoes alive in a trunk, in the proximity of moisture, for a period of ten days, and said that water was not necessary to their life, merely moisture.

Dr. Reed, in closing, said that he had the greatest sympathy with Dr. Formento in his belief that yellow fever could be transmitted by fomites, for New Orleans had suffered so severely through its epidemics. He had expected the utmost criticism of his methods in Cuba and if those experiments could not stand this criticism they were not worth much. He had expected all the criticism that had been presented as to his theory of yellow fever infection per *stegomyia fasciata*. He had left no stone unturned to produce evidences of contagion of yellow fever by fomites, but could not. The last man experimented with slept in a room, with an average temperature of about 82°, which was kept purposely damp and with no sunlight. He slept for 65 nights in this room, in infected garments, with the pillows and sheet wrung out with blood of yellow fever, in which it was demonstrated that the parasite was present. The doctor cited the epidemic of 1753, in Philadelphia, to prove that contamination was not by fomites; that when the fires in the house were started and ventilation was obstructed, so there could be no ingress or egress of mosquitoes, the epidemic lessened and gradually became extinct. He believed that this parasite of yellow fever does not belong to the vegetable kingdom, but that it belongs to the order of protozoa or some lower order in the animal kingdom.

Continuing Dr. Reed said: "I must mention one point and it is this: When a case of yellow fever enters a city where it may be propagated, a second case does not occur promptly. Please remember that fact. No one has done better work than Carter of the Marine Hospital service. Let me say right here that when we had reached a certain point in our investigation, the observations of Carter on the interval between the infecting cases and secondary cases of yellow fever were the turning point in our investigation. Carter's observations convinced me that the mosquito conveyed yellow fever. I have not a doubt on this subject after reading his splendid observations. What did Carter ascertain? Why, in some 67 cases where he could accurately note the date of the arrival of the infected case in a farm house and the development of the second case, what was the result? Were fomites or the mosquito play-

ing the part of infection? Carter's observation showed that it took from 13 to 21 days before the second case occurred. The mosquito did it."

Col. Chas. R. Greenleaf, Chief Surgeon, Division of the Philippines, spoke of **Sanitation in the Philippines**. The system of sanitation, which is so satisfactory now, was first applied only to the soldiers occupying the city of Manila, but was subsequently extended to the native towns.

In the case of smallpox, which has been greatly reduced through vaccination, the Government experienced great difficulty at first, as the insurgents would kidnap the vaccinators provided for safe guarding the health of the communities, and kill them.

There were 30,000 lepers in the Islands, large numbers freely moving about. These were treated by colonization.

Registration of doctors, dentists, pharmacists and midwives is now required.

The diseases met with in Manila are: *Bubonic plague*, *typhoid fever*, *measles*, *tuberculosis*, *tetanus*, *whooping cough*, and *beriberi*. Compulsory notification is required in all cases except *beriberi* and *tuberculosis*.

Dr. Wm. Foster Smith, Executive of the Superior Board of Health, of Puerto Rico, spoke on "Sanitation in Puerto Rico."

The area of the Island is 3600 square miles with a population short of a million. The great drawback to the establishment of sanitary measures has been the abject ignorance on the part of the native population, who are unable to read any notices that may be promulgated (even when printed in Spanish) for the safeguarding of public health.

Blindness prevails to a great extent, owing to the filthy customs in vogue by the midwives in attendance at birth. *Yellow fever* has not appeared for some time. *Dysentery*, *enteritis* and *gastro-intestinal* diseases carry off hundreds of people. *Tuberculosis* likewise prevails.

A peculiar form of *anemia*, due to an intestinal worm, is a great affliction among the natives. *Smallpox* is on the decrease, while *leprosy* and *elephantiasis* abound.

Prof. S. H. Woodbridge read the Report of the Committee on Car Sanitation. Among its many recommendations for caring for the public while travelling are:

Hard plain polished surfaces, and disuse in railway cars of carvings and grooves which furnish lodgement for dust and dirt.

Material for seat-backs, curtains, berth-bedding, etc., to be non-absorbable.

Ventilation.

Automatic temperature-regulators.

Cleansing of cars.

Removal of upholstery outside for cleaning.

Disinfection of interior of coaches.

Isolation in special compartments of cars for tubercular (or otherwise) infected passengers.

Providing for receptacles for receiving sputum, and prohibiting spitting on floors of cars.

Memorial Service for President McKinley. Held in the 74th Regiment Armory, Buffalo, N. Y., September 19th, 1901, by the American Public Health Association.

The meeting was called to order at 10 o'clock A. M., by the President, Dr. Benjamin Lee, who spoke as follows:

This day, the day which the National and State authorities have set apart as a day of humiliation in commemoration of our late lamented President, the ordinary business of the Association will be entirely given up.

There are, however, one or two matters which could be properly attended to which will take very little time before the resolutions are presented.

The Secretary will read the resolution prepared by the Executive Committee to formulate resolutions. The Chair will call upon Dr. Holton as a member of that Committee to present the resolutions of respect to the memory of the late President.

Dr. Holton:

Mr. President and gentlemen of the Association: Your

Committee appointed to grant resolutions on the death of President McKinley, beg leave to submit the following:

RESOLVED, that the American Public Health Association has received with deep sorrow the intelligence of the sudden and tragic death of the beloved President of the United States.

RESOLVED, that in President McKinley we recognize the highest type of modern civilization, a patriotic citizen, a Christian gentleman and a sagacious and enlightened statesman.

RESOLVED, that we respectfully extend our heartfelt sympathy to Mrs. McKinley in this her hour of bereavement and to other members of the family.

RESOLVED, that a copy of these resolutions be spread upon the records of this Association and given to the press for publication.

(Signed.)

BENJAMIN LEE, Chairman.

WILLIAM BAILEY.

HENRY D. HOLTON.

FREDERICK MONTIZAMBERT.

E. LICEAGA.

President:

The Chair would suggest that before the motion is put, some members may like to express themselves in regard to the resolutions, and we will call upon Dr. Wm. Bailey.

The Chair has but one word to say in this connection—he is in Heaven, we upon earth; therefore, let our words be few.

Dr. Wm. Bailey's address:

Mr. President and Members of the Association: I feel that words fail me to express the depths of sorrow that we all feel. Yet it is a sad pleasure to me to speak a word on this occasion. As expressed, I think, well in our resolution, we recognize in the late President all that is best in modern civilization in every relation in life. As a man, as a statesman, as a soldier and as a Christian, and as to his family relations, we all doff our hats when we contemplate the loyalty of this man to his afflicted wife.

Coming, as I do, from the South, I would like simply to call attention to the fact, that no man since the war—the civil war—has done as much as President McKinley to unify this country of ours. Without partisan bias, when it came to the Spanish war we find that a Wheeler, a Lee, a Breckenridge were his prominent agents in the carrying on of this war. So that to-day in the South, as never since '60, have we had such a feeling toward a President or toward the flag of our country. So for this we may be thankful for this man. The very heinousness of the crime precludes almost its mention, and yet allow me to express in this presence that this country, since its organization, has always been open to receive everybody from other climes who desired to come to us. While that is still our wish for those who come for the betterment of themselves and mankind and who desire to become Americanized, adopting the principles of this government as their own, yet let me say that the day has come when it must be expressed that we have no place in this country for those who come with a view of promulgating principles that are so much at variance with the principles upon which this government is founded, and that there is no longer a place in this country for such spirits to come and concoct their damnable curses.

Simply, then, and briefly, I would offer the seconding or the adoption of these resolutions in their full spirit, that we do recognize an irreparable loss, that we recognize in this man one worthy of our deepest love, and I am sure that we likewise congratulate ourselves and feelingly return thanks for the expressions that have come to us from our sister nations and, I might say, from the world.

Dr. C. P. Wilkinson:

In seconding the resolutions I voice the sentiments of the people of the extreme South in the section from which I come. Our city was very recently very highly honored by

a visit from our now deceased President. Our people turned to him with a smile and extended hands. They held out armfuls of flowers for the man, for the citizen and for the President. The same bells, Mr. President, that rung out paens of praise for that man are now tolling deeply as his body lies just about ready to be consigned to the tomb. There is no section of the country that feels more acutely and more bitterly the killing of President McKinley than does the South. He was their friend. As in the killing of Abraham Lincoln, in the excitement of war, the South was visited, was direly punished for any hand which she might have had in that assassination, so, to-day, Mr. President, the South mourns the loss of that President, who was, since that time, the first to extend the open hand of fellowship and ask us to join in the house of our fathers in the Union.

To-day, sir, we find no place for any reflections upon the previous history of any party, or any man in that party, but we do recognize the onward march of William McKinley towards the prosperity, towards the peace, towards the protection of our citizens alone, regardless of our State or sectional birth.

We mourn, Mr. President, to-day more than we can express, and, on behalf of the South, I join in the deepest regret that we have to pass these resolutions, but, sir, with the most heartfelt earnestness in the truth of every word they express. (Applause).

Appropriate addresses were likewise made by Mr. Bryce (Dominion of Canada) and Dr. Liceaga (Republic of Mexico).

Symposium on Tuberculosis.—Prof. Russell of the University of Wisconsin, introduced this subject in a careful yet exhaustive paper on human and bovine tuberculosis and their inter-relation. The importance of any phase of investigation relating to tuberculosis and its relation to milk is unquestioned in these latter days, when the general public is beginning to appreciate for the first time the magnitude of the problem that confronts them in attempting to lessen the ravages of the "great white scourge" of the human race.

In considering this subject it may be approached from two points of view:

1. From the standpoint of animal industry.
2. From that of public health.

Bovine Tuberculosis and Animal Industry.

The rapid extension of the disease among cattle within the last few decades has forced upon breeders and dairymen the necessity of considering this subject, whether they desire it or not. It is customary in many quarters, even yet, to decry all consideration of this matter as unnecessary, inexpedient, and harmful to the dairy interests. But as is too frequently the case, the motive for such action rests upon a financial foundation, and many breeders are averse to a calm, judicious discussion of the matter, simply because it may mean financial loss to them.

Since the introduction of the tuberculin test as an aid in the diagnosis of the disease in cattle, it has been positively determined that the malady, at least in its incipient form, is very much wider spread than was formerly supposed, but it by no means follows that all animals that react to the tuberculin test are actually in a condition in which they or their products are dangerous to man and beast.

The slow insidious nature of the disease that characterizes it in the human being is also to be found in cattle, and not infrequently an animal may be infected with the seeds of the disease for a considerable time—even a year or so—without showing in any degree physical symptoms that are manifest to even the animal expert. Such animals are

not diseased in the ordinary meaning of the term, i. e., they are not capable of transmitting the disease, either directly or indirectly, through their milk supply or meat. The affection in such cases is latent, generally confined to various lymphatic glands; but animals so affected are, however, potentially dangerous, for the latency of the disease may be overcome through the operation of various factors, and the chronic type may thus be awakened into an acute phase. It is in this way that the disease spreads slowly and unperceived through a herd. Before it has made such inroads as to cause actual death of any considerable number of animals, many more have acquired the trouble, at least in the earlier phases. Necessity of controlling its spread and eradicating it is evident for the sake of the herd itself, if from no other point of view. Successful animal industry, especially with cattle, requires that herds shall be kept free from all taint of this disease. As to treating milk Prof. Russell said pasteurization and sterilization were the two best forms of applying heat to destroy the organism. He recommended the rotatory pasteurizing machine, one of which has been used in Winnipeg for some years, as the best method of removing organisms from milk.

Dr. Good of Winnipeg, in discussing the paper said that it afforded him some relief to learn that milk is not so dangerous after all. He stated that he had been avoiding milk and all organic fluid for the past year or two, but he was glad to know that he could now go back to its use with the same freedom as in his younger days. He then moved a vote of thanks to Prof. Russell, seconded by Dr. McArthur, which was unanimously adopted.

Dr. A. J. Richer, of Montreal, contributed the next paper on the sanatorium treatment of tuberculosis. This treatment has been introduced by Dr. Trudeau in America under great difficulties, and at the present time this distinguished scientist was able to house and treat over one hundred individuals in his institution. According to Dr. Richer, the treatment is made up of rest, outdoor life, over-feeding and medical supervision. This latter was described as the keynote to success in phthisical treatment. Over-feeding was also emphasized.

The last paper was contributed by Dr. Gilbert Gordon of Toronto, and it referred to the etiology and the early diagnosis of pulmonary tuberculosis. He spoke of the early stages of the disease, and thought that we ought to be able to diagnose it before the appearance of the bacilli in the sputum. Direct inheritance he considers very rare. The inhalation of dried sputum is the most direct cause. Dr. Gordon considered that we are woefully behind in Canada in fighting this plague and more money should be spent by governments and philanthropic individuals in fighting this disease. He went carefully into the symptoms of the pre-tubercular stage and considered that a persistent cough was a very dangerous symptom.

An important discussion took place upon this topic. Dr. Lafferty warned the profession in Ontario against sending advanced cases to the Northwest Territory. Dr. Barriek of Toronto, pointed out that Ontario was leading in regard to the treatment of tuberculosis and he hoped to see the sanatorium brought with a wide open door to all conditions of life. Dr. Brett of Banff, suggested that the Association should pass a resolution pointing out to the Parliament of Canada the necessity of providing for the establishment of sanatoria for the benefit of the community.

THE NEW OFFICERS.

The report of the nomination committee was presented by Dr. W. S. Muir, Truro, N. S., who expressed regret at having to accept the resignation of their general secretary, Dr. F. N. G. Starr. Montreal, was selected as the place of meeting in 1902, and a suggestion was left with the members of the Association that they meet in British Columbia the following year. These officers were elected for the ensuing year:

President, F. J. Shepherd, Montreal; Vice-Presidents,

Prince Edward Island, S. R. Jenkins, Charlottetown; Nova Scotia, T. F. Macdonald, Hopewell; New Brunswick, Wm. Christie, St. John; Quebec, J. Alex. Hutchinson, Montreal; Ontario, Bruce L. Rlordon, Toronto; Manitoba, A. J. Macdonnell, Winnipeg; Northwest-Territories, H. G. McKid, Calgary; British Columbia, J. M. Lefevre, Vancouver. General Secretary, George Elliott, 129 John street, Toronto; Prince Edward Island, H. D. Johnson, Charlottetown; Nova Scotia, J. W. McLean, North Sydney, C. B.; New Brunswick, W. L. Ellis, St. John; Quebec, C. F. Martin, Montreal; Ontario, H. A. Bruce, Toronto; Manitoba, J. T. Lamont, Treherne; Northwest-Territories, G. A. Kennedy, Macleod; British Columbia, C. Morris, Vernon. Treasurer, H. B. Small, Ottawa. Executive Council, Jas. Stewart, T. G. Finley, J. M. Elder.

The Winnipeg meeting of the Canadian Medical Association will go down in the annals of the history of that Association as the best meeting ever held under its auspices. On the first day alone 130 members were registered and the total number at any time present reached 175, a number considerably larger than that at Ottawa last year and second in point of numbers to the meeting at Toronto in 1899. A large number of new members was elected, particularly from Ontario, Manitoba, the Northwest-Territory and British Columbia. Every province was represented at the Association meeting with the single exception of Prince Edward Island, one delegate coming as far as North Sydney, Cape Breton. The meeting was generally voted a pronounced success; and certainly the profession in Winnipeg and Manitoba and the citizens of Winnipeg more than eclipsed, in point of social functions, any previous meeting. The reception by the Board of Governors of the Winnipeg General Hospital, the reception by the ladies of Winnipeg at Wesley College, the special trip down to Old Fort Garry, where Mr. and Mrs. Calpman extended their hospitality to the members and their wives and invited guests from Winnipeg, the visit to the Ogilvie Mills, the reception at Government House by Lieutenant-Governor and Mrs. McMillan and the special trip out to Brandon through the great wheat belt of Manitoba with the entertainment provided by the ladies of Brandon,—all will stand as a series of social functions which have never been surpassed and will probably remain unsurpassed for some years in the history of the Canadian Medical Association meetings. One of the best and most important discussions took place on the formation of a Medical Defence Union; and it is very gratifying to have to record that such an organization was unanimously supported by the Association. All the leading officers of this Protective Association are located in Ottawa and Dr. Russell Thomas, of Lennoxville, P. Q., along with W. S. Muir, of Truro, N. S., is deserving of much praise for the great good work he has performed in this connection. Much regret was expressed at the resignation of the General Secretary, Dr. F. N. G. Starr, of Toronto, who has so long and so faithfully, so ably and so energetically, discharged the responsible and important duties of this position. At a time when the Association is so prosperous it is due to the new General Secretary that a united and earnest effort be put forth by all the members of the Association to continue that prosperity.

An Atypical Case of Addison's Disease.—At a recent clinic at the Beaujon Hospital, Professor Debove demonstrated an atypical case of Addison's Disease in a man of 63. (*L'Independance Medicale*, June 12, 1901, No. 23). He has traveled a great deal, and has had dysentery and malaria. His face, hands, neck, and scrotum are dark brown, and the cheeks, lips, and conjunctivae show brown spots. His spleen is normal. The skin has become hard, rugged, and dry; he is cold, and constantly exhibits "goose-flesh." This melanoderma began 20 years ago. In spite of the absence of all other symptoms, and the long duration of the pigmentation, Debove diagnosed Addison's Disease, and ordered 10 to 40 cg. of suprarenal extract as treatment.

A CASE OF GUNSHOT WOUND OF THE KIDNEY
AND STOMACH.By JOHN B. ROBERTS, M. D.,
of Philadelphia.

The report of a single case of abdominal wound has, as a rule, little value; but the injury to this patient was so similar to that recently sustained by a distinguished personage that its record may have some interest. This interest is perhaps enhanced by the fact, that in the present instance no operation was deemed necessary, though the case was carefully watched, with the possibility of operative interference always in mind. Death revealed that operation might perhaps have saved life.

A woman, aged 40 years, of known intemperate habits, was admitted to the Philadelphia Polyclinic Hospital for a self inflicted gunshot wound. A very short time before admission, she had fired at her own heart with a large pistol. There was a wound on the front of the left breast, a little below the nipple. The breast was flabby and pendulous; and on raising it, there was seen a similar wound in its posterior surface and a wound of entrance into the chest wall directly opposite this opening. The bullet had evidently gone directly through the dependent mammary gland and then into the thorax. The patient showed only a moderate amount of shock, and had a slow pulse, rapid respiration and a rectal temperature of less than a degree below normal (97.8°). There was no sign of effusion of blood in the pericardium or pleural cavity, and no evidence of abdominal injury. The rapidity of respiration (28) was accounted for by the pain and the probable interference with the action of the diaphragm. The slow pulse rate recorded (48) was either an error in observation or due to some undeterminable cause. There were no macroscopic evidences of kidney injury shown by blood in the urine; though an examination made next day showed it to contain albumin, epithelial casts, some white and red corpuscles and bacteria. Her nervousness, restlessness and muttering created the impression in the mind of the Resident Surgeon, Dr. R. Max Goepf, and in mine that she was on the verge of delirium tremens.

Careful examination of the patient led me to believe that probably the bullet had missed the heart, perforated the diaphragm and injured the liver. There was some rigidity of the upper abdomen in the liver region, but no tympany, and I was uncertain whether, after all, the traumatism had not been limited to the thoracic viscera. Intestinal perforation did not seem probable and the temperature and pulse record made internal hemorrhage unlikely. I decided not to make any operative exploration.

Six hours after admission, her temperature was 99.8°, her pulse 90, and the respirations 36. These facts still further confirmed the diagnosis of probable limitation of injury to the chest or upper abdomen, the absence of internal hemorrhage, and an intact intestinal tract. During the night, however, the temperature rose and the respirations and pulse increased in frequency, so that in the early morning the record stood: pulse 120, respiration 42, temperature 103°. These symptoms looked like those of a traumatic pneumonia or a septic peritonitis from perforated gastrointestinal tract; but no physical signs could be found of an intrathoracic inflammation, and the abdomen was not tympanitic, though its upper portion showed muscular rigidity and pain. The patient died later in the day, after being under observation about thirty-two hours.

The treatment adopted was medical and not surgical. At no time did exploratory incision into the abdomen seem to me justifiable, though I am rather radical in my views regarding the necessity of exploratory section in traumatisms of the abdomen, and do not believe in dilatory surgery in such cases.

The autopsy showed that the bullet had struck the breast one inch vertically below the nipple, entered the chest in the sixth costal interspace, and perforated the corresponding portion of the diaphragm. The thoracic viscera were uninjured, though there was some clear

serum, but no blood, in the pleural cavity. When the peritoneal cavity was opened "a large quantity of light colored partly disintegrated blood was liberated," and a number of large blood clots were seen in various portions of the abdomen. The intestines were removed and were found to have suffered no injury from the bullet. There was no congestion of their peritoneal covering, and no lymph upon them, except where there were beginning adhesions in a few places between the bowel and the omentum. The spleen and liver were uninjured.

On the lower surface of the stomach, near the cardiac pole, there was found a groove-like wound about $\frac{3}{4}$ inch long. This involved the outer coat, but had not perforated the viscous. Below the spleen was a large mass of coagulated blood surrounding the left kidney. The perinephric fat was badly lacerated at the upper end of the kidney and that organ was perforated in the middle line at the junction of the cortex with the medulla. The bullet had passed entirely through the kidney, from front to back. The kidney tissue seemed normal and contained no hemorrhages. No clots were found in the renal pelvis.

An external incision made in the back disclosed the bullet which was imbedded in the muscles of that region, opposite the first lumbar vertebra, one inch from the middle line.

Death was apparently due to slow bleeding from the wounded kidney and a septic condition of the injured structures. The wound of the stomach was unimportant. The high temperature would probably not have been present, if the hemorrhage had been the sole cause of death; and the increase in frequency of the pulse would not have been so slow, if the bleeding had been rapid. The alcoholic condition of the patient may have had an influence in raising the pulse rate and the temperature. It is possible also that bleeding was started in the night by the patient getting out of bed, unknown to the nurse, in a search for water. The thirst of which she complained may have been incited by the bleeding.

I was much surprised at the result of the autopsy, not suspecting a wounded kidney. Before the autopsy, I had attributed the death to rapid sepsis, basing the opinion on the rapid rise of temperature during the night. The post mortem findings, however, render it possible that the bleeding had much to do with the early death. Indeed it probably was the chief factor in the rapidity of that occurrence; though a septic death would probably have finally occurred. A study of the pulse, respiration and temperature is interesting.

	On admission	7 P.M.	9 P.M.	11 P.M.	1 A.M.
Pulse	48	80	90	104	112
Respiration	28	32	36	32	38

Respiration			46	42	44
Temperature			102.2°	103°	103°

A CASE OF GUNSHOT WOUND OF THE STOMACH IN
WHICH THE PATIENT RECOVERED.

By G. W. PENN, M. D.,

of Humboldt, Tenn.

Apropos of the fateful shot that ended the life of our lamented President, I wish to call attention to a case occurring in the practice of my father, Dr. J. W. Penn, now dead.

The accompanying cut (from photograph taken September 18th) is that of Alex. Mullins, the patient in question.

He is now 52 years old and still an active farmer. I quote from my father's scattered case records: He was shot at 7 A. M., May 22d, 1878, by his own pistol, his opponent having taken it from him, and hence shooting at close range. The similarity to the President's wound is apparent, since the revolver used was of 32 calibre, and the wound of entrance as seen from the cut, only about an inch lower than the shot that killed President McKinley, or to be accurate, it is one and one fourth inches to the left of the median line, and one and one half inches above a line drawn across the navel. The patient had just eaten a hearty breakfast. My father saw him about two hours after the shooting. He vomited freely as soon as shot, the matter consisting of the meal just eaten and copious quantities of clotted blood; he continued to vomit blood during the first day. Patient rested well after a hypodermic of morphine. For 11 days he was fed exclusively on the mucilage of the cactus or prickly pear, which was allowed from the first, and was permitted other forms of liquid nourishment after this time, gradually returning to a full diet. He was in bed just five weeks, and I am sorry the records are so meagre regarding the temperature and pulse, but there was never a decided rise of fever, and no evidence of peritonitis, his long continuance in bed being rather a precaution than a necessity.

A case of Pistol Shot Wound. The point of entrance is shown at the cross.

I wish to add this case to the list mentioned in an editorial of the Journal of Sept. 14th, in which Aleock is quoted as giving one case of recovery from gunshot of the stomach, out of 3000, before the days of modern surgery, and while it is not reported to substantiate the "masterly inactivity" plan of Senn and other authorities on military surgery, it incidentally illustrates the ability of nature to cope with grave conditions, the more that being an inch lower than the President's wound it would seem that both pancreas and kidney were in greater danger of injury. My father believed that the full stomach was a favorable factor in that fewer fibers of the stomach wall were cut by the ball, and hence a closer approximation of the wound edges following the contraction after emesis. As

one of the lessons of the President's case, would it not be well in such wounds to first excise the necessarily contused, and possibly infected edges elliptically, much as an ulcer might be excised, before uniting with suture? Would gangrene of the stomach wall have been so likely had this been done? The above is not said in criticism of the technique of the excellent surgeons in the case, but as stated, a possible advantage to be gained from this sad experience.

PARTIAL GASTRECTOMY FOR HEMORRHAGIC ULCER.

By L. J. HAMMOND, M. D.,

of Philadelphia,

Surgeon to the Samaritan Hospital and Out Patient Department of the Methodist Hospital, Philadelphia, Pa.

The following is the history of a case of bleeding gastric ulcer:

Family History.—Mother is living and well at the age of 67 years—father died twenty years ago, age 50, from smallpox. There were eight children, seven girls and one boy; there are living and well at present six, one having died at the age of two years from whooping-cough, another at twenty from inanition.

Personal History.—Agnes K., age 28 years, height 5 feet, 4 inches, weight 92 pounds, the seventh child of the family, had mumps, scarlet fever, measles, whooping-cough and chickenpox, all from infancy up to the eighth year, no known sequelae having followed any of these diseases of childhood, the patient having been in the best of health from the eighth until the twentieth year (weight at this time, 115 pounds); when at her work as stenographer she was attacked with vertigo and violent pains in the epigastric region, accompanied by diarrhea, the stools being well mixed with blood; there was no vomiting; the excessive diarrhea subsided in about ten hours, though for the next

Figure 1.—Ulcer of Stomach Excised.

eight days there were from three to five stools a day distinctly tarry in appearance. The patient at this time was extremely pale, with marked exhaustion, no vomiting, nor was there any pain in the region of the stomach after the first day. She was confined to the bed most of the time for the next month, the only symptoms complained of being fulness in the stomach, some pain and extreme weakness. She rallied from this attack sufficiently to resume her duties by the end of the fifth week, never, however, entirely regaining her former strength.

About one year later she was again attacked with sudden severe pain in the epigastric region, followed in a few hours (about eight) with diarrhea distinctly tarry in appearance, which continued about five months; the stools during this period were not always tarry, though the patient assures me that never a day passed without at least one of the passages containing these characteristic bloody stools.

While at the seashore where she went at this time, the diarrhea ceased and her health again improved so far as to enable her to return to her work. (This was in August, 1895.) The following March, 1896, she was attacked with severe pain over the stomach and for the first time vomited blood, the quantity of which was estimated at about one pint—five days later a second hemorrhage about the same amount. Tarry stools followed this attack for about eight days. The intense pain in the epigastric region always preceded the hemorrhage about twenty-four hours.

After this attack in March, the patient was confined to

her bed for six weeks. She lost flesh and strength from this time on for about two years; during this period she became so reduced in flesh and strength that it was impossible for her to do more than drag about the room; apprehensive of further hemorrhage, she refrained from taking sufficient food until there is but little doubt that much of this loss was due to actual starvation, and only after persuasion was she induced to take more food in a predigested liquid form, when she began very decidedly to improve and in a few months was able to return to work, continuing at it for two and a half years, or until February 15, 1901, when she was again attacked with severe pain. On the 16th,

Figure 2.—Illustrating a case of partial Gastrectomy.

another hemorrhage occurred, when she vomited from one to one and a half pints of blood—twenty-four hours later a second attack of vomiting of approximately one half pint of blood, following this about every hour for the next ten hours, she vomited blood in amounts of about an ounce; blood was passed by the bowels for about twelve (12) hours longer.

As to the source of hemorrhage, there was but little doubt that it was from ulcer of the stomach. Operation was advised at the time though it was positively declined by the mother as well as the patient herself, and the extreme exhaustion did not make it advisable to urge it at this time as the patient would undoubtedly have succumbed before the operation could have been completed. The importance of operation was however explained to the mother and advised to have performed if the patient rallied from the extreme condition in which the hemorrhage had left her. Treatment therefore consisted in placing an ice cap over the stomach, internal administration of ten grain doses of tannic acid, and feeding per rectum exclusively, the latter consisting of one and a half ounces of predigested beef juice alternating with the same amount of milk, this being prepared by adding to it one half dram of lime water and twenty grains of sodium chloride; rectal feeding being administered every fourth hour. (This method of administering milk, I have found to be most efficient, the salt apparently aiding in the digestion of the milk, while the lime water through its alkaline action prevents caseation). In addition the patient was encouraged to swallow frequently, one half dram doses of shaved ice.

This line of treatment was continued for six days; at the end of this period, in addition to rectal feeding as above indicated, the patient took per orum, one half ounce of beef juice alternating with same amount of egg albumen every four hours; rectal feeding being discontinued on the tenth day.

She improved daily and by the end of the second week was able to walk about her room, she however manifested much apprehension, fearing a return of the bleeding, and finally gave her consent to be operated upon. (At this

time examination of blood showed reds, 3,600,000, whites, 9,000).

Operation was consequently advised because of (a) the frequent attacks of hematemesis which increased both in severity and duration with each succeeding attack, the last of which was entirely beyond control by any known therapeutic agent.

(b) From the history of a well defined localized soreness to the left of the median line beneath the costal cartilages, there was reason to suspect that perforation was threatened, it being thought that the pain and tenderness which had been continuous at this point, since the last attack, were due to plastic adhesions from the ulceration having reached the visceral peritoneum.

(c) From the history of so long standing a condition, it was thought that a pyloric obstruction likely existed.

The patient was therefore prepared in the usual way and the stomach exposed through a median incision extending from about one and a half inches above the umbilicus upward toward the ensiform cartilage, incision being made from below upward instead of as is usual, from above downward, because of the abnormally high position of the ensiform cartilage, as well as the close proximity of the costal cartilages of the floating ribs (vertebro-chondral which made the precise location of the stomach uncertain.

Photograph shows the great height of the ensiform cartilage which is seen to be pointed and curved anteriorly, as well as the unusual proximity of the costal cartilages below the seventh instead of receding laterally in an oblique direction as is usual; their position is nearer vertical on either side, where they are seemingly held as far as I could determine by examination through the incision, by unusually elongated costo-xiphoid ligaments which appeared to be reflected over, holding firmly together the cartilages from the seventh to the tenth inclusive.

It will be seen that the intercostal spaces are not only unusually wide, but their costal cartilages very nearly approximate each other to within two inches of the umbilicus, the difficulties therefore of even determining the actual position of the stomach are at once obvious. It was necessary therefore, in order to inspect the stomach, to divide this firm ligamentous attachment up to a line with

Figure 3.—Temperature in a case of partial Gastrectomy.

the eighth rib, further space being procured by forcibly holding the cartilages apart on either side by retractors. By this means the stomach was brought out through the incision after dividing the greater omentum and folding it upon itself; in order to accomplish this, the lesser omentum and gastro-splenic ligament had to be put quite

thoroughly on the stretch. The subsequent steps in the operation consisted in palpation over the surface of the organ.

There were no adhesions as were expected to be found from the history of pain localized in one spot, which had been continuous since the last hemorrhage.

Palpation began at the pyloric end and consisted of gathering the entire thickness of the wall of the stomach between the index finger and thumb, and gently rolling. After a search of some minutes, the loss of substance, in the absence of uniform thickness was distinctly noted, in the same way that one would detect a hole in the inner lining of a coat by gathering together the thickness and rolling it between the fingers. This seems to me to be one of the simplest, as well as one of the most accurate means of locating loss of substance in any tissues, the walls of which are composed of layers, part of which are loosely held together as those of the stomach, the loose cellular coat between the mucous and muscular enabling one by this method of palpation to at once locate any rent that may exist even if confined alone to the mucous layer, making of course its discovery much easier when ulceration extends to a greater depth.

The seat of ulcer was in the posterior lesser curvature, and was removed by a linear incision on either side of it. After its removal, the mucous surface of the stomach was thoroughly palpated as well as inspected, this being readily accomplished by illuminating it. There was no noticeable amount of stenosis at either orifice. This fact seems to place in doubt the statement that gastric ulcers of

women, though none of these are actually demonstrable as etiologic factors, thrombosis would seem to be in this especial case the most likely cause, as the perfect encasement of the stomach within this firm unyielding cavity, when distended during the act of digestion, might readily receive sufficient trauma to interfere seriously with circulation, thus thrombosis might readily result.

The cut shows an ulcer four centimeters in length with a tendency to lateral spreading about its centre, and extending to the muscular coat. The margins of the ulcer were inverted and adherent, the mucous surface to the muscular coat nearly throughout its entire length on one side, while on the other (which was probably the source of recent hemorrhage) it was free and distinctly granular.

A CASE OF TUBERCULAR ULCER OF THE STOMACH.

By ERWIN FISCHER, M. D.,

of Pittsburg, Pa.

There being but one case of the kind that I am to report, in literature, and this by Petruschky, the following case may be of interest:

An unmarried lady, 23 years of age, with a suspicious family history of tuberculosis. She came into my care one and one-half years ago, complaining of fulness after eating, and occasionally pains in the epigastrium, and extreme weakness. By her own statement she had always been a hearty and fast eater. The lips and conjunctiva were anemic. Body fat was scarce; heart regular in action, and the second sound over the mitral area divided. The respiratory organs apparently free of disease with exception of slight roughness of the respiratory murmur over the right apex. Upon examination both kidneys were found movable, there was gastropotosis, and retroflexion of the uterus. In the hypogastric region, to the left of the median line, tenderness was elicited on pressure. The site and character of the pain were pronounced to be the same as that which gave her trouble after taking the food. A Hoffa bandage relieved the enteroptosis, but the extreme tenderness corresponding to the position of the large curvature of the stomach persisted. HCl. acidity about 2%. I decided upon putting her upon the typical treatment for ulcer, Carlsbad salt internally with hot applications locally. On account of her slight improvement this was followed by the administration of nitrate of silver, which, however, rather aggravated the symptoms. Considering the fact that neurasthenic conditions are very common in those afflicted with enteroptosis, and as there appeared to be reasons for suspecting decided nervous influences, bearing on her condition, I used electricity and similar treatment for some time longer, but in vain. Last spring the patient complained of losing flesh, and of not being able to take nourishment without pain being produced. The diet was regulated, Carlsbad salt and nitrate of silver administered with the same result as previously. I did not risk introducing the stomach tube at this time on account of the very pronounced epigastric tenderness. The unusual resistance of the ulcer, to treatment of which there could be no doubt, in my opinion, led me to suspect that the ulcer was of tubercular origin. Tubercular ulcerations of the stomach have only been noted in post-mortem examinations as complications of advanced pulmonary phthisis. In June, 1899, Petruschky published several observations in which the tuberculin test enabled him to make the diagnosis of a primary tubercular ulcer of the stomach during life, and by specific treatment attain recovery. My patient was subjected to the usual test injections, of which the second and third injection, 5 mcs. each, produced typical local and general reaction. Especially interesting and convincing was the local action, consisting each time of increased pain in the region of the stomach, voluntary, as well as produced by pressure, and followed by nausea. Besides the left apex still showed rough expiration upon auscultation, and in the

Figure 1.—Temperature in a case of partial Gastrectomy.

long standing produce stricture of the pyloric end, and, as this condition had from the history of the case at least, extended over a period of eight years, there should have been some stricture present, while, as a matter of fact, the index finger could be readily introduced well into the pylorus.

The healthy edges were brought together with fine silk by the Czerno-Lambert method, and the abdominal incision closed with two layers of sutures.

After-treatment consisted in rectal feeding only, of one and a half ounces of predigested beef juice alternating with the same amount of milk prepared as above indicated. After the sixth day the patient was given by mouth, egg albumen ($\frac{1}{4}$ oz.) and beef juice ($\frac{1}{2}$ oz.)

From the first she was permitted to wash the mouth with water every half hour when desired.

Recovery was uneventful; the sutures were removed on the eighth day. The appended chart shows the uniformly normal convalescence.

Among the etiologic factors of gastric ulcer are syphilis, tuberculosis, chlorosis (?), embolism and thrombosis; hyperacidity is said to be generally associated with the condition especially in young

supra-scapular region a few crepitant rales were combined with prolonged extirpation. Symptoms relating to the digestive organs, and especially the stomach, are not rare, as early manifestations of pulmonary tuberculosis. They are probably produced by toxins, and are a warning to physicians to be on guard against incipient phthisis, especially if they persist, and no traceable cause be found. They respond to the test injections, by producing a general reaction, but not always so clearly when the disease is so local, affecting the stomach. In this case the history and general condition of the patient distinctly indicated a circumscribed gastric affection of the nature of an ulcer. That the character of the ulcer was tubercular, was evidenced by the vain efforts at treatment and by the results of the tuberculin test. The comparatively trifling character of the pulmonary phenomena will hardly admit of claiming for them that they were the primary focus, and must be looked upon rather as a coincidence.

The regular treatment with new tuberculin (T. R.) was instituted. The doses were cautiously increased from the routine dose at the onset of 1/500 mg. of the solid substance to 20 mg. The few times that slight general reaction occurred were accompanied by local reaction on the part of the stomach. Two weeks ago the last large dose was injected. The result thus far besides the disappearance of the pulmonary symptoms has been an increase in weight, almost entire absence of pain, even on pressure, good appetite without evil consequences, in spite of her not adhering strictly to careful mastication of her food; in fact, a condition which after a typical course of treatment in a simple peptic ulcer, we should not hesitate to pronounce as recovery. This naturally does not complete the treatment, which will have to be resumed again after a few months.

I should not have reported this case as the history quoted is still incomplete, had it not been for the fact that cases of this character might be diagnosed more frequently if the profession's attention were called to their existence following Petruschky's communication. The failure of the treatment by nitrate of silver in the case of failure in the treatment of the bladder, as well as the stomach, might give rise of the tubercular origin of the affection. The tuberculin test should be used to reveal and oftentimes to heal the concealed tuberculosis which may be the source of disease of the stomach, either by direct or indirect infection.

ADDRESS IN MENTAL DISORDERS AT THE PENNSYLVANIA STATE MEDICAL SOCIETY, 1901.

by ROBERT H. CHASE M. D.,

of Philadelphia.

Superintendent of the Friends' Asylum for the Insane, Frankford Philadelphia

In recent years, there has been a marked departure from the observance of former presidents to summarize in the annual address in mental disorders the progress which had been made in this field of medical science, for the previous twelvemonth. But now, on the contrary, the custom prevails of selecting some particular theme appropriate to the occasion.

In choosing a subject to engage the attention of this meeting, it has seemed to me that your interest could be gained by the presentation of data, which can be marshalled under the title:

*PARESIS FROM THE STANDPOINT OF THE GENERAL PRACTITIONER.

This subject is presented, under the belief that it is one in which the general physician rarely takes but little interest, because the impression widely prevails that it is not a disease that concerns him

Dr. Chase has a work on General Paresis in preparation now about ready for the publisher.

greatly. This attitude is a mistaken one, because it is the disease of mental breakdown of middle life, and, the parietic falling first into your hands, as the family physician, should receive promptly your most skilful attention. At this time he is entering, you will observe, upon a very insidious and treacherous affection, and unless it is staid in its course it inevitably leads to a fatal termination. Hence, in this initial stage—this critical period—the disease should be intelligently studied by you, not alone to enable you speedily to recognize it, but for the weightier reason that at this early day the most favorable season is offered; in fact, it is the only time during its course when any treatment is at all likely to be crowned with success.

I would not presume upon the role of teacher, but if by a timely hint, or through a few suggestions, a friendly spirit can be aroused to dispel apathy in any quarter, my task will be accomplished.

It has been said, with truth, that a thorough knowledge of general paresis is a liberal education in mental disease. Some insight into its complex symptomatology may be had, when it is known that in its course no single function of the brain is free from encroachment, and that in its various phases it may exhibit nearly all of the phenomena observed by the neurologist, as well as most of those known to the alienist. Certain groups of symptoms may preponderate, cerebral, bulbar, or spinal, in variable association, as one or other region of the nervous centres becomes involved; but in the fact that the chief focal point is in the "highest nervous arrangements," all of the authorities are very fully united, and many of them further agree that the cerebral cortex is, also, primarily the affected site.

The date of the discovery of general paresis is not more remote than seventy years ago; and to French pathologists indisputably belongs the credit of having first recognized and described it as a special form of disease. There are, however, passages in the writings of Willis, the anatomist (1670), indicating a knowledge of the association of paralysis and insanity; while Haslam and Perfect, at the close of the eighteenth century, reported cases having a combination of the two series of symptoms, of paralysis and dementia, but both of them failed to appreciate, as did Willis, the clinical import of their observations. In 1815, Esquirol, under the head of monomania in his *Maladies Mentales*, noted the fatal nature of paralysis with failure of speech, but he, in common with the writers just mentioned, did not have a clear conception of general paresis as a distinct affection.

It is to the pupils of Esquirol that the distinction belongs of actually bringing to light this much disputed disease. The subject was studied with much zeal by Georget, Delaye and Calmeil, who regarded the malady as a special form of paralysis, superimposed upon the insanity; in other words, that it was a complication of an already existing disease. They observed in certain cases of insanity a peculiar form of paralysis, which was characterized by speech impairment, and by other motor disorders. In 1824 Bayle, another pupil of Esquirol, differed from other observers by formulating a new theory; he declared the affection to be a separate entity, dissociated

from any other type. He made the existence of expansive delusions its necessary distinctive symptom, assigning to it a regular course, and dividing it into three successive periods, which he named respectively monomania, mania and dementia.

Requin (1846) contended that the malady, to which he applied the prefix progressive, may exist without symptoms of insanity, conceiving the paralysis to constitute the essential part of the disease, though a certain degree of dementia was admitted to be a customary sequel to the paralysis. Other French writers confirmed this view, among them Baillarger, who took a prominent place in the discussion for many years. It was he who first termed the affection paralytic dementia, a title that has been adopted by many of the writers, both old and new. Baillarger upheld this theory to the time of his death in 1883, which postulates two quite distinct disorders, susceptible of existing associated with each other, or separately: (1) paralytic dementia, the principal disease; (2) paralytic insanity, the accessory affection (Regis). This "dualistic theory" has many adherents to the present day.

Again, some other authors, for instance, M. Ball, of Paris, look upon general paresis as a generic term, embracing a variety of diseases, differing in etiology, symptoms, course and final termination.

Hence, we see that there have been in the past several theories respecting the nature of general paresis, of which the prominent ones may be briefly stated as follows:

- (1) As a complication of insanity.
- (2) As a distinct form of insanity.
- (3) If not as a group of cerebral or cerebro-spinal affections, at least as a paralytic dementia, to which is associated more or less frequently, and under various conditions, insanity. (Regis.)

It is remarkable to find, in examining the works of the older writers, that, with all their acumen, they failed to perceive the symptoms that pointed to the slow and insidious nature of general paresis at its onset. It was not until Lasèque, in 1853, described an initial stage, comprising symptoms that had not been regarded as typical, that the medical world was apprised of this feature, but even then his discovery was allowed to be forgotten, because of a lack of conformation. Folsom calls attention to the fact that it was not until the appearance of Professor Ball's work, in 1883, and that of his former Chief de Clinique, M. Regis, in 1885, that any clear statement of the very insidious and obscure character of the first symptoms of the disease can be found in French special medical literature.

Since 1876, the leading German writers on diseases of the brain, especially Wernicke, Schnle, Kraft-Ebing and Mendel, have described the beginning of general paresis as being simply a change of character quietly developing; and, later, so slight are the impairments of the intellect as to admit of the patient continuing his avocation without exciting special notice.

The English and American authors, in years past, have not, as a rule, set a just value on the very early and obscure character of the symptoms of general paresis, although Savage, writing in 1884, mentions

that, when he observes certain vague, variable nervous symptoms, he is disposed to give a guarded prognosis; and Mickle, in 1886, states that "in the history of many a case do we find that some moral or other mental change in the patient, some perversion of the affective sentiments, has been noticed long before the acknowledged onset of the disease." Until a recent date, the impression has been almost universally among alienists and in the medical profession generally, that paresis is a disease in which the signs should be expressed by the classic symptom-complex of early difficulty of speech, pupillary anomalies, muscular tremor and uncertain gait, accompanied, on the mental side, by intellectual weakness, and, in many cases, by delusions of grandeur.

This clinical picture, through brief, is a faithful portrayal of the symptoms of the established disease, but you, as the medical adviser of the family, must deal with these cases ere they assume so distinct a form, and sometimes long before such phases develop.

The very early signs of general paresis are ill-defined, and often so vague that they may deceive even the very elect (the neurologist), whom you may call in consultation. There are two accepted forms of onset, the gradual and the sudden. In the latter there is no forewarning before the storm breaks; an attack of acute mania (beginning abruptly), or an epileptiform or apoplectiform seizure, may be the signal, ushering in the disease.

It is, however, a fact that is well attested that the beginning is seldom sudden. In the gradual onset the changes, at first, are few and slow; but there are certain marks, which may be traced, of a progressive diminution of mental power, and a few indications of a constantly increasing incoordination of particular groups of muscles, followed later by a gradual paralytic invasion of the entire muscular system, which, if detected in time, furnish a means of delay and a ground of hope to this otherwise desperate situation.

The manifestations, at first, are usually mental, although, occasionally, the mental and motor symptoms occur simultaneously; and it is possible, also, for the somatic phenomena to appear first.

It is well to keep in mind when forming a diagnosis in a suspected case, that if the patient can be taken at a disadvantage, the defects to be sought are more readily brought to view. If the symptoms are sly, the patient, for example, should be examined after he has passed a sleepless night, or when he is emotionally perturbed, or excited. In the initial period, the symptoms generally, both mental and motor, do not advance uniformly, but come and go, depending on the rhythm, which characterizes all nervous diseases. In the conditions just mentioned, the physician is much more liable to find evidences of amnesia, or other mental impairment, or to observe the early tremor about the mouth, or other physical signs, which might be absent when the patient is calm and composed.

To pursue our theme in a sequential order, we will examine:

- (1) The early mental phenomena.
- (2) The early physical symptoms; and

(3) Some suggestions as to treatment, applicable to the initial period.

The form that is taken by the disease is significant, whether it be depressive, expansive, or demented, as it tinges very early the ensemble of the patient's mind. A slight melancholy or seeming discouragement in the subject is accounted for by his friends as the effects of some physical cause, or it is passed over by them unnoticed; or an obtrusive and unusual egoism may be falsely interpreted by them, or referred to, only, in the way of fault-finding. This, and similar situations, should evoke close scrutiny by the physician, and if no cause be found to account naturally for the patient's conduct, it remains for him a guide-board to other more intricate signs that the disease may display. At first, the patient is conscious of ill-feeling, that he is not in his normal condition, but as the disease advances, he loses the power of discrimination, and he then insists that he is entirely well. Savage refers to a physician who correctly diagnosed his own case as that of paresis, but soon forgot his misfortune in the blighting effects of the advancing disease. In another case, the patient pointed to the top of his head, and said that, like Swift, he was "going first at the top." For the moment he appeared emotional, but in the feeling of *bien-être*, which was developing, he forgot his troubles when induced to speak of his fine capabilities. Lewis tells of a talented mathematician, in whom the early symptoms were intense despondency, and sudden lapse of attention and memory. Often when solving a problem, he would cover his face with his hands and, rising from his chair with a pained expression, hurriedly remark, "It's no use, it's all gone." He frequently confessed how painful such a state was to him, realizing most fully the sad condition of his mind, before the final disruption occurred.

Generally, among the earlier signs is a lack of mental vigor. This may be manifested, on the part of the subject, by a loss of interest in his business, or an inability to attend regularly to his affairs. It may be impossible to keep his attention fixed for an extended period, and, at the same time, he may be able to follow out in a fair way the routine of his daily duties, if the duties be not too perplexing.

However, the inability to fix the attention is attended with restlessness of spirit, which in turn develops into an alteration of character and disposition. The patient seems erratic and unduly excitable, especially over individual interests. In this change of character, Brierre de Boismont, a long time ago, first called attention to a failure, or perversion of the moral sense, as one of the most important of the prodromic symptoms. In rare instances, even years beforehand, some moral perversion, such as an act of theft or indecency, has occurred, before any other sign of the disease has been detected. Very early in every case, the ethical motives of the patient are prone to be those of a lower, a more selfish, nature than he has held formerly. De Boismont gives the case of a man who began thieving eight years before the diagnosis of general paresis was made. A reputable plumber, among the writer's cases, was arrested for fraudulently tapping a city gas main, without a certificate,

nearly a year before other discernable symptoms appeared. In another case, a sedate married man was arrested, three years before he was adjudged insane, for indecent assault on a colored woman, and he was emulged of a large sum of money before released from his unfortunate plight. Berkley relates the interesting history of a railroad official, who, well-known for his thrift and business ability, concocted a scheme of fraud, which proved to be the first symptom of the disease. Going to a small town in Western Virginia, where he was known, he took a room at the principal hotel, purchased several properties, and told his friends that a railroad was to run through the place, and that he had bought the properties, so as to forestall the projectors of the road, as they wished to locate their depots and offices on these sites. He was so well known for his business shrewdness that a syndicate was formed by the local people, and the land re-bought at an advance of thirty thousand dollars. He left the town with his gains, which he dissipated within a few days. It is not an infrequent experience of asylum life to have patients presented at the door suffering from this disease, who have previously been subjected to imprisonment for misdemeanor, or petty crimes.

Moderate exercise often causes unwonted fatigue of mind and body. Confusion of ideas, temporary forgetfulness, an inability to control the mental processes, as in the past, give occasion for annoyance to the patient, and result in discouragement and irritability on his part. The mental symptoms, at this stage, are seldom considered of any importance by the family or friends.

Transient amnesia, which is apt to be a conspicuous symptom, deserves a passing word. It is noticed early in the patient's writing, in unusual misspelling, omission of letters, and soon of words and parts of sentences, especially does this occur if he be tired. To the same cause may be attributed a forgetfulness of the proprieties of life, and through it many incongruous acts result: A gentleman walked into a drawing room without removing his hat, and lighted a cigar; a woman coming out of a church took a handful of silver from a plate held at the door, without any attempt at concealment; a gentleman in good standing called on a policeman to assist him in disposing of some goods, which he had just purloined from a grocer's wagon in the street; a married woman began to undress herself by a country roadside; and a woman ordered a pair of trousers for her husband, a bricklayer, to be made of *moiré antique*. (Sankey.).

Furthermore, the feelings are intensified, and the patient becomes readily excitable, often about trivial matters. Temporary loss of self-control follows, with an exhibition of temper, on occasion, beyond the degree that is wont to be displayed, even in one nervously fatigued. Sometimes a change in the affection occurs, so that persons previously dear to the patient become abnoxious to him.

Long before this catalogue of mental symptoms has been completed, the physical usually make their appearance; in some cases, as has been said, the two appear together.

The patient may complain of being "nervous."

Insomnia is frequently an early trouble, or the sleep may be very light and unrefreshing, often disturbed by dreams and nightmare. This sign needs to be inquired about, for the patient is apt to regard it as an unimportant matter. There are certain diffuse symptoms that should claim critically the attention of the physician. Conspicuously among these should be enumerated flashes of heat to the head, and alternate pallor and flushing of the face; momentary pains of neuralgic character, felt in different parts of the body, or a localized pain, as a facial neuralgia, or a burning spot on the trunk, or limbs, and also hyperesthesia, followed by tingling of the skin, sometimes anesthesia or paresthesia. To this group may be added others, equally frequent and suggestive; headaches, sincipital, temporo-frontal, or occipital; a capricious appetite and irregularity of the bowels.

Some patients have the feeling that they are walking on air, and are not fatigued after exercise that may be somewhat excessive, while others are easily tired, and experience but little relief from rest. The circulation may be sluggish and congestive attacks not infrequently occur. Ballet reports that one of the most brilliant French novelists of recent years was energetically treated for several months, with douches, as a neurasthenic, before the obvious signs of general paresis were observed. Dr. Stearns, of Hartford, tells of a patient who was unable to attend to business on account of restlessness, and was treated by the family physician for malaria. Again, a woman patient had neuralgic pains six years before mental symptoms appeared. Whenever these pains subsided, as they frequently did, then occurred numbness, and, at times, loss of sensation in feet and ankles.

Close examination reveals, in a great many cases, early pupillary changes—myosis with irregularity and inequality. Myosis is one of the most common of the earlier symptoms, and while its value is a variable quantity with different observers, the apparent constancy with which it appears, in the first period of the disease, associated with the inequality of the pupils, must obviously direct the physician's mind, in these cases, to the probable diagnosis of paresis. Griesinger, long ago, pointed out the fact that pupillary anomalies, the contracted, irregular, sluggish or unequal pupil, may antedate other symptoms for a long time.

These signs, you observe, are indefinite; many of the symptoms would indicate neurasthenia, with or without hysteria, or uncomplicated cerebral asthenia. In this early stage of the disease, to which we refer, there is fear that the physician will fail to catch some of the more subtle signs, unless he be on his guard, and take care to see the patient at different times of the day, and under varying circumstances, as rest, especially a good night's rest, may greatly improve his condition. Folsom observed a marked change in the tremor, which appeared in the handwriting of a doubtful case, after the tiresome effort of a long walk; and Lewis describes how a patient was thrown into convulsions by pressing him into close mental application, in the solution of a mathematical problem.

The first stadium passed, the malady becomes,

sooner or later, better defined in the development of symptoms of greater diagnostic value. On the mental side, the feeling of well-being passes into that of extreme elation and egoism, expending successively into a delusional state of wild scheming and extravagance. On the somatic side, the symptoms advance *pari passu*. Tremor and weakness in muscular control increase, and, as the muscles of speech are the highest in order, they are the first to be affected. The muscles about the mouth are less controlled, the fibrillary trembling of the tongue becomes apparent, together with a slight slurring of the speech, or a hesitating and jerky mode of speaking. Words with a repetition of linguals, as "unintelligible" and "illegible" are impossible of a clear enunciation.

The handwriting takes up the tale. The early tremor shows incoordination. This, however, is not enough to decide the case, for tremor may result from other causes—from age, alcoholism or other nervous defects. But in this instance there is added to the tremor an inability to control the attention; the formation of words grows more irregular, final letters are omitted, reduplications occur, and especially when the patient is tired he indites against himself convincing evidence of both mental and motor failure.

The control of the larger groups of coordinated muscles, controlling gait and station, may continue for a time unimpaired. But the finer and more highly organized muscles are more quickly affected by ataxy; the delicate movements required in engraving, drawing and embroidery are readily affected, and occupations, depending on nice adjustment of the hands and fingers, as watch repairing, piano playing and many of the mechanical arts, must at this stage be abandoned by the paretic.

In making a review of the therapeutic history of general paresis, one is clearly convinced, with substantial proof, of what a mighty struggle there has been waged against this formidable disease. It would seem that there is scarcely any drug or remedial measure, at all applicable, that has not been brought to bear against it. It has long been the opprobrium of medical science that her art fails to strike down the morbid cause of degenerative diseases, on whatever organ of the body the attack may be made. Can there be an exemption in the intractable nature of this disease, so essentially degenerative, that is not shared by other affections of a similar kind.

This query must await the response that scientific medicine of the future shall bring to its solution. It is to the general physician that we earnestly look, for it is he, who is first called into the case, at its very inception, and at a time when the greatest hope for relief may be reasonably expected. Time is an important factor, as in many other affections, and the earlier that treatment can be applied the better.

Meynert held the theory that, preceding and causing the diffuse cortical encephalitis, there is a functional vaso-motor disorder, which he considered curable. My task to-day will be concluded by laying before you briefly a bare outline of treatment in the early stage, such as the indications, from the light of experience, have suggested.

It is necessary to keep in mind the cause of gen-

eral paresis and remove these if possible. The transitional life of the paretic may be compared, in a measure, with the small mountain stream, which, gaining volume and force as it goes, is at last transformed in its onward course into the raging torrent. Could the controlling influences of moderation be applied at the source, how different, in each case, would be the result. Hence, coition should be in great part discontinued; all alcoholic stimulants prohibited; worry and strain of every kind removed; work, both mental and physical, reduced to a wholesome degree; and the most favorable hygienic conditions possible put into practice. Active physical recreation, judiciously pursued, is generally beneficial, combined, as it may be in selected cases, with the partial rest treatment, massage and hydrotherapy. Abstemious habits of living, early hours, watchful care of sleep, a suitable diet, and very careful attention to the bowels should be enjoined. In cases with a history of syphilis, specific treatment should be prescribed, although but little may be expected from this course after the disease becomes established, if it be not, in fact, actively injurious.

The bodily functions should receive attention, the general health built up, with tonics if necessary, and such plan of treatment instituted for this end as best meets the views of the individual practitioner. Some authorities recommend here an alterative tonic course. But rest, fresh air, moderate exercise and regular hours will be found to be, as ever, the great restorers of energy.

Even in suspected cases, where the diagnosis has not been made out, it is well to advise rest and removal from the daily occupation and surroundings. This should not, however, be in the form of extended travel, with its accompanying hurry, annoyance and excitement, for this is attended with more harm than good. There can be no doubt that a change of environment and an avoidance of worry and excitement will always be of benefit. If this should involve loss of salary, or be a serious interference in business, so that the anxiety resulting would be of greater injury to the patient, then a lightening of labor may be insisted on, together with the adjustment of the home life. The patient should be shielded from whatever may cause anxiety or worry, and freed from all such strain. The paretic's brain should be put, as it were, in splints.

There remains for the practitioner one additional duty, a duty that is broader than the interest of the individual case. He should at all times remember his responsible relations to the community at large, in his office, as conservator of the public health. Let this be an important duty, looking to the welfare of posterity, that he shall use his influence to the utmost for the eradication of any tendency towards hereditary predisposition. With less forethought than the breeders of cattle, we never raise our voices against the "sowing of tares" in the indiscriminate marriage of neuropathic persons.

Seldom has there been a time when the teachings of the medical profession have fallen upon more willing ears than to-day; the public is very responsive to medical precepts, and shows a disposition to follow far more closely these injunctions than is realized by the average physician. And, while gen-

eral paresis is not so largely a hereditary disease, as some of the other forms of insanity, yet even here the results of a weakened nervous constitution tell on the next generation with no abatement of force. A very large percentage of adolescent and juvenile cases of general paresis are those who have been born syphilitic. Folsom, in this connection, says: "My own experience leads me to the conclusion that in those cases of general paresis without a previous history of syphilis, the vast majority occur in families in which there have been cases of insanity, epilepsy or apoplexy." Regis has many times found consanguinity in the ancestors of paretics.

The effect in subsequent generations may be a different type of nervous disease, or it may result merely in a reduced moral and intellectual capacity, but it is now very generally agreed that "defect, deterioration and vitiated quality of brain" must and do follow nervous excitement and nervous exhaustion of previous generations.

It is then your duty, let me say, in conclusion, to enlighten and to warn; and in every case, where it is possible, to emphasize the dangers resulting from the overstrain and the overliving of twentieth century civilization, and, by every prophylactic measure in your power, to meet this disease over which too long has been inscribed:

"All hope abandon ye who enter here."

THE PROGRESSIVE MUSCULAR ATROPHIES.*

By EDWARD E. MAYER, A. M., M. D.,
of Pittsburg, Pa.

The steady progress which neurology has made in the last half century is shown very strongly in the history of the progressive muscular atrophies. It was in 1849 that this subject was opened by Duchenne and Aran's classical work, and not many years after, that Cruveilhier showed that progressive muscular atrophy was a spinal cord disease and soon after him that Charcot found that it was the ganglion cells of the anterior horn which were at fault. The next advance came in the differentiation by Charcot of a group of cases under the name of amyotrophic lateral sclerosis, which he considered to be due to changes in both the anterior horns of the spinal gray and in the lateral tracts—a view which Gowers combated, claiming that both diseases are one according as to whether the cells or the lateral tracts are first involved.

A type of progressive muscular atrophy, preceded by a pseudohypertrophy in certain muscles had also been described and all cases were grouped either under the Duchenne-Aran (the amyotrophic) form, or under the pseudohypertrophic (the myopathic) form. Investigation, however, revealed many types of progressive muscular atrophy in which no spinal changes were discoverable, and in time we had described a juvenile type (Erb), an infantile type (Duchenne), a facioscapulohumeral type (Landouzy-Dejerine), a peroneal type (Marie, Tooth), a pelvic type, etc. This was the condition when closer observation revealed the fact that these clinical pictures were not independent diseases, but were

*Read before the Pittsburg Pathologic Society, March 18, 1901.

simply different forms of the same disorder and were grouped by Charcot under the name of the primitive muscular myopathies, and by Erb as the progressive muscular dystrophies. Attempts have also been made to separate various hereditary types. All the dystrophies were formerly supposed to be hereditary, an observation which time has not borne out. Some, however, still cling to the idea that there is a particular hereditary form of muscular dystrophy (the Leyden-Moebius type), but we cannot even acknowledge this much. Hoffman gives four forms of hereditary muscular atrophy: 1. A Duchenne-Aran type. 2. A form beginning in the pelvic region and extending to the limbs from the trunk. 3. An infantile, bulbar, paralytic, facial type, and 4. a transitional type.

Three general forms of progressive muscular atrophy have been recognized, one in which the muscular changes are primary, the myopathic form or progressive muscular dystrophy; one in which they are secondary and due to changes in the anterior horns, the myelopathic or amyotrophic form or spinal muscular atrophy; and one in which the primary degeneration is in the peripheral nerves, the neurotic or neural type. Such a classification was and remains simple and convenient, but time has shown that neither clinically nor pathologically does it always hold true. Transitional and mixed types are by no means exceptional; symptoms, which were thought to be characteristic of one type, have been found to occur in the others; and what is most important, investigators have shown that even the pathologic muscular changes are not positive proof of the existence of one or the other type.

The neuron theory asserts that that part of the anterior cord extending from the anterior cells to the muscle fibre is one in function—the lower neuron, and that a second or higher motor neuron extends from the anterior cells upwards through the lateral tracts. It is therefore conceivable that a degeneration of the centre—the ganglion cells, if of moderate severity and of long duration, must impair the function of the muscle nerve-ends, and that an atrophy of the muscle must in such cases coexist with an atrophy of its centre. Dr. Spiller has summed up our knowledge on this point in asserting that: 1. Cases of muscular atrophy occur which present the well-known localizations regarded as characteristic of the different forms of muscular dystrophy. In the large majority of these cases, the spinal cord and peripheral nerves are normal. 2. In other rare cases presenting the clinical features of muscular dystrophy, the nervous system is more or less involved. 3. The histologic changes in the muscles are not pathognomonic of any form of atrophy. 4. It is proper to regard muscular dystrophy as a disease usually distinct from spinal muscular atrophy, but transitional forms connect the myopathic and myelopathic types of atrophy.

Before proceeding in detail concerning the various pathologic and clinical changes, we wish to give an account of three cases lately seen by the writer, which show the difficulty in diagnosis:

CASE 1.—Jos. G., Hillsville, Ohio. Italian parentage. Aet. 18. Fruit dealer. Both parents well according to patient and examination of father revealed nothing abnormal. Family history entirely negative. Had severe attack

of scarlet fever when 8 years of age. About eight years ago, he noticed a weakness in his knees, would often sink down to the floor without being able to control himself. He soon afterwards noticed that walking was becoming difficult and that he would tire soon in walking any distance. His legs began to feel numb and he claims that they are so still.

Present condition: An undersized, badly nourished boy. Looks like a child of 14. No stigmata of degeneration. Internal organs are all normal as are also the cranial nerves. Facies normal. Backward and lateral movements of head normal. No dizziness, vertigo, paresthesias or headache. Sleep normal. No spasms or convulsions. Slight tremor (coarse) in hands. Fibrillary tremor in shoulder and arms. No fascicular or choreic movements.

Acromion process lowered, scapula nearer to middle line than normal (8cm.) Winged scapula. Arm cannot be raised farther than shoulder and but slightly backward. Upon attempting to lift patient by armpits the acromion processes are elevated above ears. Shoulder abnormally movable in all directions. Upon extending arms and then attempting to press velar surfaces together, very little power is perceptible. Extension of arms is difficult, spindle shaped arm with difficult flexion and pronation. Thenar and hypothenar are atrophied as are also interosseous spaces. Pronounced lordosis. Protrusion of abdomen. Duck-like waddling gait from exaggerated pelvic movement. Cannot straighten up from reeling position without climbing up upon himself. Thighs extended with difficulty. Cannot raise heels or stand on tip toes. Slight plantar arch. Flat footed. Cannot walk 25 feet without resting. Quantitative decrease of electric excitability without qualitative changes. Reflexes absent. Fibrillary tremor in deltoid and biceps and in supraspinati. No rigidity anywhere. Speech normal. General sensation normal with exception of feeling of numbness in the limbs. Objectively no disorder of sensation was found. Station co-ordinate.

—We have then an 18-year-old boy who has an extensive atrophy and paresis of a slowly progressive nature. The alterations are general and embrace chiefly the shoulder-girdle, pectorals, triceps and biceps, supinator longus, interossei, thenar and hypothenar muscles, erectores trunci, abdominal muscles, gluteals, gastrocnemius and peroneal muscles. The atrophy is symmetrical. Fibrillary tremor. No reaction of degeneration.

Into what class of the atrophies shall we put this case? It is as far as could be ascertained not hereditary as are most of the dystrophies, fibrillary twitchings were present which are not supposed to occur in the dystrophies, and there was no sign or history of true or pseudo-hypertrophy as occurs in the dystrophies.

As in the neural form, the atrophy seems to have begun in the lower extremity, but there is no history of its attacking the toes first and then extending up the leg from muscle to muscle. The atrophy of the pelvic and lumbar muscles were, to judge from their condition at present, affected soon afterward. Indeed, the patient, viewed from this point alone, resembles more the pelvic type of dystrophy. The slight sensory disorder as occurs in this patient is, however, I believe, only noticed in the peroneal or neural type. The simple quantitative decrease in electric excitability without even a partial reaction of degeneration, and its onset in early years speak for the juvenile type of the dystrophies. Again, the distal parts of the upper extremity are more involved than is usually the case in the dystrophies. The time of its onset with the localization of the atrophy at the beginning of the disease speak for the hereditary form, yet no hereditary history is present.

Fibrillary tremors were formerly supposed to be

characteristic of the spinal form, yet so many observations have occurred of its presence in the dystrophies and of its absence in spinal cases that this symptom—hitherto supposed to be one of the most important differential points—has no longer the same value. It is believed, however, never to be as extensive in the dystrophies as in the myelopathies. In this case, it was only present in the deltoid, biceps, and supraspinati.

The time of onset and hereditary character have also not been proven to be absolute diagnostic criteria. Cases of dystrophy have been described as occurring in aged individuals and cases shown after death to have been spinal cases were of an hereditary nature.

Even the electric reactions, supposed to be diagnostic, have not stood the test. The reaction of degeneration need not necessarily be present in the spinal type of progressive muscular atrophy, and has been noticed several times in true cases of dystrophy. This is very easily explainable. In a chronic case where some muscle may still be intact, their reaction will hide the absence of qualitative changes in the atrophic bundles. Again a muscle may be so completely degenerated as to give the reaction of degeneration even though the centres in the cord are intact as the stimulus does not reach them from the muscle even if it did have no muscle to act upon.

Cases vary greatly also as to their course. Although myelopathic cases are generally acute and dystrophic cases chronic, exceptions have been noted. The pseudo-hypertrophy, if present, is a rather absolute symptom of dystrophy. In our case it was not present. We must content ourselves, therefore, in regarding this clinically as a mixed type, although more of a dystrophy than an atrophy. Pieces of the gastrocnemius and triceps were removed and examined microscopically. They will be described and shown later.

CASE II.*—Marie K., Aet. 7. Seen by kindness of Dr. Wm. B. Ewing. German parentage. Family history difficult to elicit, as father, the only one accessible, is very illiterate. He himself is and has been always well and examination of him reveals nothing abnormal. Three children, Marie being the second. Other two well. One died in childhood, from tuberculosis. Mother was strong and healthy when child was born. Died later, aet. 32, from a gynecologic operation. Marie was never able to walk. High grade imbecile. General weakness in muscles which is said to have commenced when the child was 2 years old, was first noticed in the arms, most marked in the left. Child is of average size and of poor nutrition. Very anemic. High arched and narrow palate. Marked myopathic facies. The lips are thick, prominent and protruding, the facial muscles and forehead are smooth and expressionless, the eyes are almost always closed or but slightly open. The right levator palpebrae superioris acts better than the left but it is difficult to get the child to execute any movements upon demand. The lips can be closed but it generally holds the mouth open with the lower teeth showing. In laughing and crying the mouth is drawn laterally but hardly any folds appear upon either side. The angle between the neck and shoulders is very long. The muscles on the anterior and lateral aspects of the neck are slightly palpable, those on the back are atrophic. The head is held stiffly as is the whole body. The child remains perfectly motionless in any position in which she is placed. If the head is thrown back, it falls until it touches the vertebrae and the patient cannot raise it again.

*I am indebted to Drs. Ewing and Henniger for much of the clinical history of this case.

The atrophy of the sternocleidomastoid with intact trapezius which this child presents is not common. Only Erb, Reinhold, Landouzy, and Pick have reported similar cases.

Weight, stripped, 25 pounds.
Height, 36 inches.

	R.	L.
Circumference of chest at nipple	43 3/4 cm.	24 1/4
" " " at xyphoid	50 cm.	25
" " " abdomen	48 cm.	24
Circumference of forearm 10 cm. below olecranon,	R. 8 cm., L. 8 cm.	
Circumference of upper arm 8 cm. above olecranon,	R. 10 cm., L. 8 cm.	
Circumference of upper arm, 20 cm. above olecranon,	R. 12 cm., L. 12 cm.	
Circumference of thigh 15 cm. above patella,	R. 26 cm., L. 26 cm.	

Greatest circumference of lower leg, R. 12 cm., L. 12 cm. The pectorals almost entirely gone, also the biceps. Trapezius atrophied. Peculiar hardness of deltoid and infraspinatus region. Spindle-shaped arm with atrophy of supinator longus. Active motion of upper arm, forearm, and waist very deficient. The arms are in a flexed and abducted position. On passive motion, the arm can be drawn down until an angle of about 160 degrees is reached where it stops with a jerk and all efforts are unavailing to extend it any farther. This is due to contracture of muscle and ligament and not to any rigidity. The hand is in a position of abduction and slight flexion. Attempts to adduct it are difficult on account of contracture. Fingers can be flexed easily but cannot be extended beyond a certain angle, second phalanx is flexed toward the first. The thumb is slightly flexed under the hand instead of being in a position of opposition.

The hip-joints are flexed and abducted, the legs are flexed at an angle of about 60 degrees. Attempts at extension are possible until an angle of about 140 degrees is reached when the leg resists all further efforts. Flexion is free. Feet are in a position of equino-varus, with deficient extension. Atrophy of all the extensors and anterior tibial muscles. Slight lordosis in sitting and recumbent position. If patient could be made to stand, the lordosis would no doubt be very prominent. Peculiar hardness of muscles of thigh. The thigh muscles are in a condition of pseudo-hypertrophy. No fibrillary tremor; absent abdominal, plantar and deep reflexes. Kernig's and Babinski's signs negative. Decreased quantitative reaction to electricity. No reaction of degeneration. The paralysis is everywhere symmetrical and flaccid. The nerve trunks were neither thickened nor sensitive. Pulse 120 and vibratory. Glossy skin and retarded growth of hair. Urine 1023, excess of urates and phosphates. Abdomen swollen with enlargement of mesenteric glands. Temperature ranging between 99° and 101°F., tubercular in nature.

Here we have apparently a case of facioscapulo-humeral dystrophy (Landouzy-Dejerines' type). The peculiar immobility and apparent rigidity of the child was so striking that at first glance the case was thought to be one of diplegic infantile cerebral palsy. Closer examination, however, soon re-

moved this possibility. There was no actual rigidity, no cranial nerve-palsy, no increased reflexes, no history of convulsions, no post-paralytic phenomena.

Palpation showed a peculiar hardness of the muscles such as is found in myositis, but the clinical history excluded this disease. It may, in passing, not be amiss to mention that Jacoby believed pseudo-hypertrophic dystrophy to be due to a chronic inflammation involving both perimysium and muscle tissue and called the process a progressive hyperplastic myositis. Poliomyelitis could also be easily excluded.

Taking up this case, then, as one of progressive muscular atrophy, we find many peculiar features. Its onset at an early age would incline us to believe it to be of an hereditary or familial nature, yet the father is positive that she is the only member of the family affected. Again, Landouzy-Dejerine's type of dystrophy is of slow progression, yet this case seems to have run an acute course. Although this case presents the typical facial and shoulder-girdle atrophy of the Landouzy-Dejerine type, it differs from typical cases in the advanced atrophy in the lower limbs. Indeed, the generalized symmetrical atrophy in this case with the pseudo-hypertrophy in the thighs and not in the calves, as is generally the case, and the early appearance of contractures, is most peculiar. Landouzy-Dejerine claimed that their type of dystrophy is never accompanied by pseudo-hypertrophy, but this has proven false.

CASE III.—J. K. Aet. 23. Painter. Family history negative. About 3 years ago noticed a weakness in hands so that he had to grip his brushes very hard to hold them. Is not positive in which hand this weakness first began but believes it to have been in the left. This weakness gradually progressed until he was compelled to stop work, which was about 18 months ago, when he was first seen by me at the College clinic. He complained also of pains in his limbs and as he had been a painter, lead poisoning was suspected. The extensors, supinators and muscles of the upper arm were involved and it was looked upon as a case of Remak's upper arm type of lead palsy, although the atrophy of the small muscles of the hand and of the interossei was well marked, more so than is usual even in those cases of saturnine neuritis in which these muscles are involved. But 12 months later after a thorough treatment he presented the following picture:

Complete atrophy of the small muscles of the hand of the interossei, of the adductor longus pollicis, biceps, brachialis internus, deltoid, triceps, supinator longus, and brevis, pectorals, the deep muscles of the trunk (erector trunci) glutei.

There was no sensory disturbance objectively or subjectively.

There was also a fibrillary tremor, and a reaction of degeneration could be elicited in a number of muscles. The progression for one year after the supposed cause of his paralysis has been removed, the involvement of the triceps, supinators, thenar muscles, etc., which is atypical of lead palsy, the absence of any benefit from treatment, and the absence of any sensory disorder made the diagnosis one of progressive muscular atrophy.

At one time it had been thought possible to distinguish the dystrophies from the amyotrophies by the muscular changes. Theoretically, this should be the case, but observations have proven its failure in many cases. The spinal type of atrophy was supposed to cause a degenerative atrophy with granular disintegration, the primary muscular type of atrophy a simple atrophy with intact striation and hypertrophy of some fibres. But in some cases in which the autopsy showed spinal changes, the muscular examination revealed a simple atrophy and in

other cases a hypertrophy. Some claim that in these cases the spinal changes are secondary. In other cases again where the muscular changes were supposed to be typical of the spinal form of progressive muscular atrophy, no spinal lesions were discoverable. It has been thought that possibly our present methods of examination are at fault and that nutritive cellular changes occur in the anterior horns which are not discoverable by our present methods of examination.

It is known that simple cutting of a nerve will produce a simple atrophy of it and will be followed later by degenerative changes. The integrity of the ganglionic cells in the anterior horns, it is known, depends to some extent upon the integrity of the periphery which it innervates. We can also assume in some cases that excessive stimulation of the ganglion cells may in time produce degeneration of the peripheral parts without causing any lesion of the ganglion cells.

The pieces of muscle taken from Case 1 were stained by Weigert's, Marchi's, Delafield's and van Gieson's methods. This specimen presented a marked increase in fatty tissue which had in some places completely replaced the normal structures and in other regions was interspersed by some muscular fibres, mostly broken and fissured and showing vacuoles.

The arterioles were markedly enlarged with thickened walls. The muscle-spindles were normal. Numerous intramuscular nerve-fibres colored intensively in the Weigert preparation. The Marchi specimens revealed an extensive lipomatosis.

In Case 2, we found a few hypertrophic fibres, a simple atrophy of many fibres, increase of the nuclei and a few fissured fibres. There was a marked proliferation of the interstitial connective tissue.

The specimens of this case were prepared by Drs. Ewing and Burns.

Many regard the absence of fat-drops characteristic of cases of dystrophy, but numerous observations of their presence in such cases have been made. As myelin also gives the black reaction with osmic acid, and as the protoplasm of muscle-fibre contains a fatty substance, Marchi's methods must be used with caution.

The muscle-spindles, which were intact in both these cases, are, according to the most recent investigations, end-organs which have a special sensory function, being most probably connected with the so-called "muscular-sense." This has not yet been proven, but we are at least satisfied now that they are a normal structure and not an embryonal defect or retrograde degeneration as was formerly thought.

These first two cases illustrate the difficulty in assigning cases to any particular form of muscular atrophy. That the sharp differentiation between the different types is often impossible is accepted, but the significance of symptoms individually or collectively has not yet been shown. Many neurologists are trying to find a neuropathic basis for the dystrophies as well as the myopathies, and look upon them as tropho-neuroses, in which the form or type of cellular change is still unknown. In other words, the impairment in nutrition of the ganglion-cells, invisible to our microscopes at present, causes changes in the muscles which we are able to detect.

Others believe in an embryonal predisposition of the nerve and muscles to malformations and defects, but the experiments of Lenonowa and Petren seem to show that the "embryonal predisposition of the muscles is independent of the nervous system." In want of more exact knowledge, therefore, we can still cling to the idea of a primary muscular disease as no investigator has as yet disproved this.*

POSTDIPHTHERITIC URTICARIA.

By JAS. J. WALSH, Ph. D., M. D.,

of New York.

One of the objections to the use of diphtheria antitoxin which carries most weight in the public mind is the fact that after its administration an urticarial eruption occasionally occurs. Whenever urticaria is noted in cases treated with diphtheria serum it is invariably attributed to the effect of by-products in the antitoxin. It seems worth while then to report a case in which though no antitoxin was employed urticaria developed at just about that stage in the disease when the eruption would probably have occurred if antitoxin were employed.

It seems not improbable that a slight urticaria or erythematous eruption occurs oftener than is reported and has been overlooked because cases untreated by antitoxin are now rare and are usually under the observation of those who would not care to give any special significance to the occurrence of the cutaneous symptoms.

The patient was a girl of about twelve years of age, suffering from a mild form of diphtheria. The throat appearances were not enough of themselves to justify a clinical diagnosis of diphtheria. There were some discrete patches of exudate, especially on the left tonsil. The fever reached 101.5°, the pulse 110. A culture, taken from the throat, however, showed the presence of diphtheria bacilli and the case was reported to the Board of Health and quarantined by their directions.

A number of subsequent cultures were made from the throat, and, according to the health authorities, Klebs-Löffler bacilli continued to be present in the mouth and pharynx for several weeks.

The patient suffered from a previous attack of diphtheria some three years ago. At that time diphtheria serum was employed. The father, a newspaper man, had, as have so many of the literary folk, opinions of his own in medicine. He was persuaded beyond all possibility of change of opinion that, as the result of the administration of the serum on that occasion, the child's throat contained delicate ever since. He had frequently expressed the opinion that he would not permit the use of diphtheria serum if the disease should develop again. At the time of the child's illness he was away, and the child was in charge of a female relative, who hesitated to take the responsibility of allowing antitoxine to be employed, knowing as she did the father's objection to it.

As the case was a mild one, I consented, under the circumstances, to treat it without antitoxin, though with the distinct understanding that if serious symptoms should begin to show themselves, antitoxin would be employed. On the evening of the third day the affection seemed to reach a maximum and began to subside almost by crisis. On the evening of the fourth day, while the child was being transferred from one bed to another for the night, some urticaria was noticed on the parts exposed for the moment. Some itching spots developed on the ankles and on the lower arms. At this time the patient was practically convalescent from the diphtheria.

During the fourth day the exudate had disappeared from the throat, and on the fifth day the temperature was

nearly normal. On the evening of the fifth day there was another attack of urticaria, that lasted as on the preceding day, for about half an hour. At this time the child's temperature and pulse were practically normal and the appetite was beginning to return.

In a word we seem to have had in this case an urticaria that corresponded at least in certain respects with the urticaria that develops after the injection of diphtheria antitoxin. It occurred during the time when nature by her vital reaction was just succeeding in neutralizing the toxin of diphtheria present in the blood. It would almost seem that as in the case of the diphtheria serum certain accessory physiological principles were manufactured in the human system at the same time with the neutralizing principle which modified the course of the diphtheria, and that these by-products aided by external irritation were the cause of the urticarial eruption. The urticaria occurred as is usual in these cases at points where the exposure to the air and the friction of garments produced a certain amount of cutaneous irritation. This was sufficient to predispose to the nervous edematous condition we know as urticaria.

In the light of its significance as regards eruptions produced by the protective serum obtained from the horse this case seems especially interesting. It suggests the idea that urticaria and other cutaneous eruptions should be looked for more carefully in diphtheria. We do not as yet know the reasons for the occurrence of such eruptions. Even in seemingly normal individuals very slight disturbances of digestion are sufficient to produce them in the predisposed. That they are due to an idiosyncrasy in most cases we are convinced by the fact that even slight indulgence in so harmless an article of diet as strawberries may produce decided urticaria, that quinine in very small doses may have a similar effect, and that even small amounts of ordinary shellfish may be followed by an excessive urticarial reaction.

With regard to the urticaria, erythema and other skin lesions which follow the administration of diphtheria serum, idiosyncrasy of the patients and perhaps meteorological conditions would seem to have much more to do with their causation than anything in the serum itself. In a careful series of observations on alternate cases of diphtheria treated with six thousand and with two thousand units of diphtheria antitoxin, the New York City Board of Health found no more tendency to cutaneous eruptions with the larger dose than with the smaller one. In Boston immense doses of serum have recently been employed in seemingly hopeless cases of diphtheria and at times with excellent results. From forty to eighty thousand antitoxin units have been administered within three days and yet the patients have as a rule not suffered anymore from cutaneous lesions than those to whom much smaller doses were given. Certainly the amount of the cutaneous eruptions bore no direct ratio to the amount of serum administered and the skin complications never seemed to prove a contraindication to the use of as large a dose of serum as the physician might care to employ.

The cutaneous manifestations are often accompanied by corresponding conditions of the mucous

*A complete discussion of this question will be found in Pick's article in the 1. Heft, 17th Band of the Deutsche Zeitschrift fuer Nervenheilkunde which also gives a good bibliography.

membrane. These give rise to definite symptoms that have been recognized in many cases. For these too the employment of large doses of serum does not seem to make matters worse. At times albuminuria is noticed at the beginning of diphtheria and at times only after the disease has run its course for several days. In a certain number of cases the albuminuria apparently develops only after the administration of the diphtheria serum. In these cases the antitoxin was supposed to be an irritant for the kidneys, as was assumed also for the skin and the albuminuria was supposed to correspond to the urticaria and erythema. We know that the albuminuria is usually due entirely to the diphtheria itself. The experience in Boston was that when the albuminuria was very marked the administration of large doses of the serum was the best remedy to lessen the kidney symptoms. The neutralization of the toxin of diphtheria seems to reduce the amount of irritating material that the kidneys have to eliminate and so proves ideally therapeutic for the condition.

It is probable that careful study of the conditions produced by the diphtheria itself will free the diphtheria serum from many of the suspicions which have hitherto been attached to it. It has been the custom, so far to a very great extent, to assume that every unusual symptom, which developed after the administration of diphtheria serum, was directly due to the serum. Some of them are undoubtedly due to anomalies in nature's protective reaction against the toxins of the disease. Many of the others find their true etiology in the secondary infections which so often accompany diphtheria and so often give rise to the mild pyemic symptoms that we are accustomed to see not infrequently in so-called rheumatic conditions, under almost the same circumstances.

Obliterating Phlebitis of the Hepatic Veins.—Rendu and Poulain report the rare case of an obliterative phlebitis occurring in the hepatic veins, in a man of 35. (*Bulletins et Memoires de la Societe des Hopitaux de Paris*, June 6, 1901, No. 19). After some months of gastric symptoms, he noted that he was emaciating, and that his abdomen was increasing in size. Later epistaxis occurred frequently, then a sudden chill appeared, and he came to the hospital. The conjunctivæ were injected and jaundiced. He had some fever, his abdomen was tympanitic, with some ascites, and there was tenderness about the umbilicus. The subcutaneous veins of the abdominal wall were markedly dilated. The liver was normal in size, but the spleen had enlarged. Diagnosis was extremely difficult. Cirrhosis of the liver seemed most probable. Before death it seemed possible that a gastric neoplasm existed with secondarily enlarged glands compressing the vena cava. The autopsy, however, showed phlebitis of the hepatic veins. These were obliterated, thus destroying about 4/5 of the liver circulation. To overcome this, the collateral circulation was overtaxed, with the gastric symptoms, the dilated superficial veins, and the ascites resulting. There was no sclerosis of the liver at all, nor was any tumor found in the stomach. The stomach and spleen showed sclerosis, probably from the amount of alcohol taken by the patient habitually. This may explain the phlebitis of the hepatic veins, causing a condition of hepatic apoplexy. [M. O.]

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended September 28, 1901.

The Cerebrospinal Fluid After Spinal Cocainization.—The use of the subarachnoid space for the purpose of producing general anesthesia, without loss of consciousness, by the injection of cocaine after lumbar puncture has resulted in much careful study concerning the physiological action of the drug when thus introduced, the cause of the post-anesthetic symptoms and the application of the method to general surgery. We have twice referred to the dangers of this method of producing anesthesia during the current year (*Philadelphia Medical Journal*, Vol. vii, No. 3, p. 91; No. 8, pp. 359 and 360); once after reading a paper by Richardson, of Boston, and the second time concerning a résumé by Tuffier, of Paris. At the meeting of the *Société de Biologie*, held June 22, 1901, (*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 27, 1901), Ravaut and Aubourg reported the results of a study of the cerebrospinal fluid after spinal cocainization. Although, fortunately, this method of producing general anesthesia has not resulted in many deaths, headache, vertigo and vomiting have been noticeable post-anesthetic complications, sometimes severe enough to cause alarm. The authors, with the idea of lessening the intensity of the headache, have made a second lumbar puncture several hours after the operation, hoping to remove some of the free cocaine from the cerebrospinal fluid and to diminish the tension of that fluid, if possibly it was under increased pressure. The second lumbar puncture seems to have had the result desired, that is, it has lessened the severity of the headache. Furthermore, it was noted that the more the headache, the greater was the pressure of the fluid in the subarachnoid space. In cases of very intense headache, the authors were able to withdraw 20 cubic centimeters of turbid fluid, which, as a rule, flowed in a jet. On the other hand, in cases of slight headache, they obtained a small quantity of clear fluid which dropped from the trochar. In the turbid fluid, which evidently existed under considerable pressure, histological examination showed the presence of polymorphonuclear leukocytes which, in some instances, formed a true clot of pus in the bottom of the centrifuge tube. In other cases, the inflammatory reaction

was so marked that a fibrin clot formed after the fluid was allowed to stand for a time. The number of the leukocytes seemed to vary according to the intensity of the headache. At the same time, in nearly every case, even when there was no post-anesthetic headache, a very slight polymorphonuclear reaction was noted in the cerebrospinal fluid. Indeed, out of twenty-one specimens examined several hours after the anesthesia, the fluid was found absolutely normal once only. In those patients in whom an intense reaction was shown, repeated lumbar puncture showed that in from eight to twenty days the polymorphonuclear reaction gave place to lymphocytic reaction, and this, in turn, disappeared, leaving a normal fluid. This is exactly the course of events that is noted in those cases of acute infection of the meninges that end in recovery. This is not a reaction of infection in the case of spinal cocainization, because, of course, all aseptic precautions have been taken in preparing the solution and in doing the operation. After excluding all sources of infection, the authors concluded that the cocaine itself produced the reaction and that its action on the pia mater and the arachnoid was similar to that of a toxin, thus explaining all the inflammatory, exudative and diapedetic phenomena observed. Clinically, headache is the manifestation of these changes. The authors think that their study shows that, on account of the rapid disappearance of the exudate, the fears that have been entertained concerning spinal cocainization are not justified. From the clinical viewpoint, Tuffier has already stated that the method of producing anesthesia by the subarachnoid injection of cocaine is perfectly safe. We can hardly agree with such dogmatic statements. A substance that acts like a toxin and that produces anatomical changes similar to those produced by an acute infection of the spinal meninges cannot be perfectly safe. General anesthesia by chloroform, ether or nitrous oxide is not perfectly safe. Deaths have occurred from the administration of all these substances, and every patient who inhales any of these for the purpose of producing general anesthesia takes a certain risk, small, it is true; but nevertheless, a risk. And so

with spinal cocainization, the study here reviewed confirms our opinion, previously expressed, that while the danger is reduced to a minimum when minute attention is given to all the details of the administration, let the vigilance be relaxed, and accidents become imminent.

The Search for the Parasite of Cancer.—The problem of the discovery of cancer has occupied so much attention lately, that there has been danger of forgetting the results obtained by accurate observers. It must not be forgotten that this problem, in spite of the work of Gaylord and Schuler, is perhaps not now much nearer elucidation than it has ever been. Parasites of cancer have been discovered so often by men who are apparently convinced of their absolute authenticity, that the modern sceptical medical man will require the strongest evidence and the most thorough confirmation before he is convinced. Indeed it is not impossible that the problem will never be solved. It would seem the easiest thing in the world to determine the parasite of small pox. The lesion is circumscribed and specific, and yet it still escapes us. The thousands and hundreds of thousands of sections, cultures and what not that have been made at the Pasteur Institute for the purpose of detecting the organism of hydrophobia, made with the most elaborate appliances, and by masters of bacteriological technique, have been utter failures, and yet, therapeutically, small pox and hydrophobia are both, to a large extent, under our control.

Newcomb has done well to call our attention to the fact that the discoveries that seem most imminent are usually those that are never made, and he instances, as of course a mathematician would, the tri-section of an angle, the squaring of a circle, and the doubling of a cube, and it may be that these problems are not more difficult than the discovery of the parasites of small pox, hydrophobia, and carcinoma. It behooves us then to turn to clinical experiences in order to ascertain if possible what benefit is to be derived from the methods of treatment already in vogue.

The Treatment of Cancer.—In a recent address before the Medical Association of Halle, Leser (*Münchener medicinische Wochenschrift*, August 13th, No. 33) has given the results of his experience with 529 cases which were subjected to operation or other methods of treatment at his hands in the decennium from 1890 to 1900. Of these, 392 cases were certainly malignant tumors, and of these 392 cases he has been able to determine the outcome in 305. Seventy-eight have survived for varying

periods of from two to eleven years—that is, 19% of all the malignant cases, a remarkably large and most encouraging proportion. Leser calls attention to the fact that apparently the most fatal forms of carcinoma are those of the tongue and the esophagus, and it is interesting to note that 29 of the cases that have survived were of carcinoma involving the gastro-intestinal tract or the rectum. What methods, we are justified in demanding, have produced this very favorable statistical result? Leser believes in two things: early diagnosis, and radical operation; and the latter he performs as soon and as thoroughly as possible. Apparently he does not hesitate to operate upon any portion of the body, resecting carcinomata from the stomach or intestines, or extirpating the rectum with perfect sang froid. In carcinoma of the stomach he believes that our present methods of diagnosis according to the usual methods, are so inadequate and unsatisfactory that, in exceptional cases, an exploratory operation is not only justifiable, it is imperative. This is radical, and yet to our mind it seems good doctrine, until, at least, our friends, the pathologists, have furnished us with a canceroin that is actually curative. In regard to cases apparently too far advanced, Leser is also radical. He believes in operation, if it offers the slightest chance for cure or for ameliorating the condition of the patient, or in the most desperate cases, in the hope that, if nothing else is accomplished, at least the patient will die sooner and more easily. He vigorously condemns the policy of certain so-called frank and honest surgeons who tell their patients that they can do nothing for them and send them away. Even in the last stages of malignant tumors, the patients may be encouraged and relieved of pain, and if they are abandoned by the regular physician they are only too likely to fall into the hands of charlatans and quacks, who are more likely to increase their misery, and are certain to deplete their purses. Taking it all in all, Leser's article is encouraging. We can do something already to cure carcinoma, and it is not unlikely that in the future improvements in diagnostic and surgical technique will enable us to control the majority of all cases. A point that it seems to us has been too greatly neglected, is the possible prevention of carcinomatous infection by the careful sterilization of all discharges from the ulcerative carcinomatous surface. This would include the vomitus of gastric carcinoma, and the fecal evacuations of all forms of carcinoma of the gastro-intestinal tract.

Smallpox in Philadelphia.—There is undoubtedly more smallpox in Philadelphia than is desirable, but there hardly seems occasion as yet to be unduly alarmed over the situation. Last week there were

sixty new cases reported with two deaths. As we have pointed out not infrequently in these columns, smallpox has prevailed in many parts of the United States for several years past in an exceptionally mild form, and it is to be hoped that, if Philadelphia is destined to have an epidemic of the disease, it will not be an exception to this rule. The desirability of wide-spread vaccination, however, is evident, and we have been glad to note that there is quite an extended demand for it among the people.

This should be encouraged by physicians everywhere. The law requiring all school children to be vaccinated or to show satisfactory scars is being universally observed. If there is any one thing proved in preventive medicine it is the efficacy of vaccination. This is no time, with the disease at our doors, to stop to debate the question with the few wrong-headed individuals who hold out against this beneficent practice. Such persons fortunately are rare in this city, and their opposition, which is mostly only verbal, will not materially affect the well-nigh universal custom.

Children as Carriers of Tuberculous Infection.—

A very interesting series of experiments has recently been carried out by Dieudonné, (*Münch. med. Woch.*, 1901,) for the purpose of determining to what extent children crawling on the floor are capable of infecting themselves by conveying tubercle bacilli from the dust to the cavities of the nose and mouth. For this purpose he made a number of experiments by carefully rubbing the hands and the cavities of the nose with small wads of cotton, then soaking these wads in bouillon and making cultures, inoculations and stains from them. In all cases he endeavored to examine children living in the houses with parents known to be suffering from tuberculosis. Altogether he investigated 15 children, and of these two proved to be bearing infectious tubercle bacilli, that is to say, in one case two guinea pigs inoculated with dust from the hand died. The mother of this child of 15 months was suffering from tuberculosis, and her expectoration contained tubercle bacilli. In the other case the bacilli were found both upon the hands and in the nose, and the father of the girl of 18 months had tuberculosis with bacilli in the sputum. The extreme importance of these investigations cannot fail to impress every reader. The danger of allowing children to creep upon the floor in any place where it is possible that tubercle bacilli should exist, is, we believe, a subject for serious consideration. Not only may they infect themselves, but it is quite possible that they could infect other children, or even adults. The very large proportion—2 out of 15; that is, over

13 per cent.—of the small number of children examined, is quite startling. Until we can teach the laity to be more careful than they are, such investigations are only another argument in favor of the segregation of consumptives.

Serumtherapy in Diphtheria.—At the recent meetings of the Medical Societies of the Paris Hospitals, the antitoxin treatment of diphtheria has again been discussed. First Voisin and Guinon described an epidemic of diphtheria in the Salpêtrière Hospital among idiots and epileptics. (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, June 13, 1901). Prophylactic injections of antidiphtheritic serum were given to all those exposed to the contagion, 10 c.c. to those over 10 years old, 6 c.c. to the younger children. After that but four cases appeared, all mild in character, without fever or enlarged glands, and with small, thin membranes which quickly disappeared. One severe case developed, however, two weeks later, ending fatally in 24 hours. This shows that the prophylactic action of the antitoxin, while efficacious, is not of very long duration. In the discussion which followed, Variot alone failed to agree with Voisin and Guinon in the good results to be obtained from the use of antidiphtheric serum employed prophylactically. Barbier and Lobligeois discussed the prolonged, recurring and relapsing forms of diphtheria. (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, June 20, 1901). In severe epidemics of diphtheria, ordinary doses of antitoxin seem to have but little effect. Either the disease is not benefited, though not necessarily made worse, or temporary relief follows the injection, with a recurrence of symptoms later. Relapses frequently occurred in the recent epidemic at the Trousseau Hospital. Large initial injections of antidiphtheritic serum were given and these were repeated often. Out of 325 cases, membranes persisted over three days after the injection in 50 patients; in a few cases they persisted until the twelfth day. Injections of from 10 to 40 c.c. were given on admission, repeated upon the second or third day. In 15 cases new membranes formed during the week following the disappearance of the first membranes, even though repeated doses of antitoxin had been injected. In false membranes situated upon spots other than the tonsils and pharynx, staphylococci and streptococci were generally found with the diphtheria bacilli. Very large doses of antitoxin were injected when tracheo-bronchitis occurred, or with the signs of grave intoxication, especially before paralysis or bulbar symptoms developed. Yet death followed, even though 105 c.c. of antidiphtheritic serum had

been injected. They reported a large number of cases in full. Méry stated that, in diphtheria secondary to measles, large injections of antitoxin are also necessary to produce any effect. (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, June 27, 1901).

The Perilous Adventure of an Old Medical Book.

—The problem of what becomes of all the old books has had a curious light thrown on it by a recent occurrence in Philadelphia. In a large paper mill in this city a great pile of waste paper was being passed into a machine in order to be reduced to pulp. One of the proprietors who happened to be standing by, saw a rather dilapidated old book on the heap, and picking it up observed that it was a Latin work on surgery. Thinking it might be of value, he rescued the old tome and brought it to the editor. It proved to be a copy of the second edition of the Latin translation of the complete works of Ambrose Paré. The title page was unfortunately torn out and the old vellum binding had been torn off, but otherwise the book was in excellent preservation. It was published at Frankfort in 1594, and its full title (which we have verified by comparing the book with the copy in the Library of the College of Physicians) is:—"Opera Chirurgica Ambroisii Paracii * * * A Docto Viro, plerisque locis recognita et latinitate donata, Jacobii Guillemeau, Francofurti, MDXCIII."

The first edition of Paré's collected works was in French, published in 1575 at Paris. There were at least twelve editions issued in the original French up to 1664, besides the editions in Latin, German, Dutch and English. The copy thus rescued from the maw of the paper machine cannot be considered extremely rare, but it is at least too venerable and too valuable a book to be ground up into bits. The query now arises, how did this aged book (more than three centuries old) find its way into a Philadelphia paper mill? Is this another case of imperial Caesar dead and turned to clay? Has Ambroise Paré so fallen from his high estate that his venerable relics are to be converted into a few cent's worth of pulp? Think of it. Three hundred years of dignified Latinity sacrificed to make a piece of modern blank paper!

The Health of the Sultan of Turkey.—A curious psychological study of the Sultan, Abdul-Hamid II, is presented in a recent work by Georges Dorys. The author, who seems to have had unusual opportunities for studying his subject, describes the Padi-shaw as a chronic neurasthenic; one, indeed, who has advanced into a state of monomania; a victim of the delirium of power, suffering from that type of men-

tal perversion which is known by the French as the "Persecuting-persecuted". According to Dorys, the Sultan's mental and nervous state is due entirely to his environment, which is a curious medley of grandeur and slavery, autocracy and superstition, luxury and squalor, imperious sway and grovelling ignorance. The political and social conditions which surround the present Caliph are perhaps unprecedented; while they have some things in them to suggest the imperialism of ancient Rome and the oriental glamour of mediæval Baghdad, they are on the whole a mere relic of barbarism—an anachronism and a sort of vaudeville, kept going not by any internal vitality, but by the mere jealousy of the European powers. When and how soon some stupendous crash may come cannot be foretold—but the mere uncertainty, and the strain of trying to be Sultan, have told sadly on the nerves of Abdul Hamid. He lives in a state of nervous tension in which the fear of assassination is the great motive power of his life and of his policy. He dies a thousand deaths in trying to avoid one. Dorys says that the haunted potentate has even studied the latest of all the sciences—bacteriology—and as a consequence has become a sort of mysophobiæ. In everything he sees a germ, and magnifies its power for evil beyond even the speculation of modern pathology. A new name has even to be invented for the mental disease of the imperial paranoiac, and he is said to suffer from "microbiophobia".

It is worth while to recall that the Sultan's brother and immediate predecessor (who is still living) is insane, and that the Sultan inherits a tendency to phthtisis from both his father and his mother. Considering the unhygienic surroundings and peculiar personal habits which are supposed to exert their influences on every Sultan, it is perhaps remarkable that the house of Osman has continued in direct descent for more than six hundred years.

Medical Bulletins.—We publish elsewhere a clipping from the *British Medical Journal* referring to some criticisms by Sir Dyce Duckworth, contained in a letter to the *London Spectator*, upon the medical bulletins issued by the attendants on President McKinley. Sir Dyce Duckworth shows plainly that it is easy to criticise from a distance, and also that he has little appreciation of the extreme tension of public feeling and anxiety in this country while the President was lying ill. This was not a question merely of taste. Details from the sick chamber are not always pleasant reading, and when published in the daily press in all their baldness they are likely somewhat to offend the sensibilities of some people. In a case such as the President's, however, there was every reason why a full and frank statement of

the symptoms and treatment should be given to the public. To have acted otherwise would have been to expose themselves to well merited criticism, and the physicians and surgeons in the case showed their good judgment in nothing more than when they took the public into their confidence.

Reviews.

Nervous and Mental Diseases. By Archibald Church, M.D., Professor of Nervous and Mental Diseases and Head of Neurological Department, Northwestern University Medical School; and Frederick Peterson, M. D., Chief of Clinic, Department of Nervous and Mental Diseases, and Clinical Lecturer on Psychiatry, College of Physicians and Surgeons, New York. Third Edition, Revised and Enlarged. Handsome octavo volume of 870 pages, with 322 illustrations. Philadelphia and London; W. B. Saunders & Co., 1901. Cloth, \$5.00 net.

In our review, in this journal, of the first edition of this work, we called attention to the fact that the book is not the joint work of the two authors, but consists of two separate treatises, the first on nervous diseases by Dr. Church and the second on mental diseases by Dr. Peterson. This plan is, of course, still adopted in this edition, and it has many advantages, as the purchaser thus obtains really two text books within the same covers. We have little to say in addition to the praise which we expressed for the first edition. We regard the work as admirably done both by Dr. Church and by Dr. Peterson. The authors announce in this edition that the book has been thoroughly revised in every particular, that new subject matter has been added, that old subject matter has been re-arranged wherever necessary, that a number of new illustrations have been introduced, and that other changes have been made in order to bring the work fully up to date. As these changes are necessarily scattered all through the text and have not been especially indicated, it is impossible for us to criticize them in detail, but we have no doubt that they are in accord with the general good character of the work, and serve to maintain its high standard. We observe that Dr. Church persists in speaking of a decussation of the seventh nerve, an error which we pointed out in our former review. In his present edition, however, he evidently means the decussation of the neurones which unite the seventh nerve nuclei in the pons with the cortex of the brain. These neurones, however, do not contain any part of the seventh nerve, because the seventh nerve consists properly of the lower order of neurones which have their cell bodies in the nuclei in the pons, and the axis-cylinders of which compose the nerve trunk proper. This trunk proper of the seventh nerve below the nucleus does not decussate. This is a point on which it is desirable to be perfectly clear, because students especially might be confused by not distinguishing between these two orders of neurones. We have found nothing else in the work to especially criticize, but, as we have already said, a great deal to commend. [J. H. L.]

The Diagnostics of Internal Medicine. A clinical treatise upon the recognized principles of medical diagnosis. By Glentworth Reeve Butler, A. M., M. D., Chief of the Second Division, Methodist-Episcopal Hospital; Attending Physician to the Brooklyn Hospital, etc. 1,059 pages, 246 illustrations and charts, 5 colored plates. D. Appleton & Company, New York, 1901.

This work, which deals not only with semiology and symptomatology also considers the diagnosis of individual diseases usually included in the province of the practice of medicine. The special chapters relating to diagnosis are well written, the material being presented in a clear, terse style, well adapted to the requirements of the student. The part devoted to physical diagnosis is clear, and shows the latest knowledge and opinions in relation to the causation of rales and murmurs. The book is profusely illustrated, and here is perhaps the only adverse criticism which we should be compelled to make. In our judgment there is absolutely no necessity for presenting nude female

figures to represent signs and symptoms of disease. In a medical work this, in our opinion, can be done diagrammatically as well, if not better. The artificial lines dividing the chest are better illustrated upon the male than upon the female thorax. The book is well printed; the illustrations are good, and the student will find much of value expressed in easily understood language, which will make his conceptions of the intricate problems of diagnosis plain and more readily remembered. We predict a large sale for the volume. [J. L. S.]

Introduction to the Study of Medicine. By G. H. Roger, Professor in the Faculty of Medicine of Paris. Authorized Translation of M. S. Gabriel, M. D. New York: D. Appleton & Co. 1901.

This work, which the author claims is particularly written for students, may be read by every practitioner of medicine with profit. The material is handled in such an interesting manner that the reader seems to be perusing an interesting scientific work without appreciating at the time that he is learning or relearning many things of importance in his every day work. Professor Roger presupposes that the beginner in medicine is acquainted with many branches correlated to the great study of medicine. This may be true of European students who enter upon the study of medicine. It is, however, only exceptionally true of the American student. Thus, in reading the chapters upon physical agents and chemical agents it is taken for granted that the student already has a knowledge of physics and chemistry. The book is well translated, and printing and paper all that could be desired. [J. L. S.]

A Text-Book of the Practice of Medicine. By Dr. Hermann Eichhorst, Professor of Special Pathology and Therapeutics and Director of the Medical Clinic in the University of Zurich. Authorized Translation from the German Edited by Augustus A. Eshner, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic; Physician to the Philadelphia Hospital; Assistant Physician to the Orthopedic Hospital and Infirmary for Nervous Diseases. In two volumes. With 169 illustrations. W. B. Saunders & Co., Philadelphia and London, 1901.

Eichhorst's Practice of Medicine is a classic wherever the German language is spoken, and it is surprising enough that the work has not been rendered into English before this. The first work published by Eichhorst is a large one in four ponderous volumes. This was condensed into one volume by Eichhorst, of which the work before us is a translation. It is, however, more than a mere translation, for the editor has adapted it to the needs of the American student and has done it well. The printing, paper and illustrations (many new ones are added) are all that could be desired. [J. L. S.]

Transactions of the American Electro-Therapeutic Association. 1899-1900. F. A. Davis Co. Philadelphia. 1901.

This volume contains the proceedings of the last two meetings of the American Electro-Therapeutic Association, at which over forty papers were presented, not one of which was of extraordinary worth. Some electro-therapeutic novelties were reported, such as the electrostatic treatment of rheumatoid arthritis and neurasthenia, by Snow; mercuric cataphoresis for cancer, by Massey, etc., the value of which time only can determine. Among the few papers of interest to the ordinary physician are those upon "Electricity in Respiratory and Cardiac Failure," by A. D. Rockwell, and "The Treatment of Uterine Diseases with Electricity," by Félix La Torre. [M. O.]

An International System of Electro-Therapeutics. Edited by Horatio R. Bigelow, M. D. Second Edition. Revised and brought up to date, with several New Departments embodying the most recent developments of the science. Edited by G. Betton Massey, M. D. Thoroughly illustrated. Royal Octavo. Pages x-1147. Price net, delivered, Extra Cloth, \$6.00; Sheep, \$7.00; Half-russia, \$7.50. Philadelphia: F. A. Davis Company, Publishers.

This large volume contains the manifold uses to which electricity has been applied in the effort to cure disease. Nothing thus far discovered in the domain of electro-

therapeutics, either good or bad, seems to have been omitted by the thirty-seven contributors, many of whom are specialists in electro-therapeutics. Electricity is fully described and its uses are explained, with many details, which will puzzle the general practitioner; while to later developments, such as electricity in the treatment of aneurysm, the cataphoresis of mercury in cancer, and the Röntgen rays, entire new chapters are devoted.

The initial chapter, a historical sketch of the rise of electricity by J. Mount Bleyer, will interest the layman as well as the physician. W. J. Herdman briefly explains the necessity for the special education of the medical man in electro-therapeutics, while electro-physics and electro-physiology are treated in full by A. W. Duff and A. P. Hrubaker. Of interest to the zoologist will be the chapter upon Animal Electricity by Wesley Mills. Dr. Massey's intricate article follows, containing a full description of the services to be obtained from the galvanic current. The faradic current is described by Henry McClure, while Max J. Stern gives a concise and comprehensive review of the Röntgen rays. Electro-Diagnosis, by W. F. Robinson, will be easily understood, while the good accomplished by cataphoresis, a subject of which the ordinary physician generally knows but little, is demonstrated by Frederick Peterson.

The rest of the book is divided into three almost equal parts, giving the uses of electro-therapeutics in gynecology and obstetrics; in diseases of the nervous system, of the abdominal and thoracic viscera, and of childhood; and in surgery. Among those who contribute gynecological or obstetrical articles are Grand and Famarque, A. Tripler, A. H. Golet, J. M. Baldy, F. H. Martin, J. H. Kellogg, A. L. Smith, Cole, Jarman, and Grandin, E. L. H. McGinnis, and G. B. Massey. The nervous system is discussed by C. E. Riggs, W. J. Morton, W. M. Leszynsky, and Morton Prince; the alimentary tract by A. D. Rockwell; intestinal occlusion by Larat; the lungs and heart by N. S. Davis, Jr.; and pediatrics by Mary P. Jacobi. In the section upon Electro-Surgery, L. A. W. Alleman has an article on Ophthalmology; C. E. de M. Sajous on Rhino-Laryngology; D. D. Stewart on Aneurysm; R. Newman on Hypertrophy of the Prostate; J. I. Parsons on Cancer of the Uterus; G. B. Massey on Mercuric Cataphoresis for Cancer; J. Byrne on Electro-thermal Surgery; Henrietta P. Johnson on Facial Blemishes; and P. S. Hayes on Skin Diseases.

The volume is singularly free from typographical errors. The system of lettering each section of the book, and of then giving numbers to the pages of each section, will confuse the man who seeks one article in a hurry. Nor is it clear why Parsons' article on Cancer of the Uterus is placed in the section upon Electro-Surgery, and not in that upon Gynecology and Obstetrics. While a most prejudiced estimate of the value of electro-therapeutics is gleaned from the perusal of this volume, there seems no doubt that it will find a place as a book of reference both for the general practitioner and the specialist. [M. O.]

Medical Bulletins.—Last Saturday's *Spectator*, (*British Medical Journal*, for October 5, 1901), contained a letter from Sir Dyce Duckworth commencing in rather severe terms upon the communications made to the lay press during the late illness of President McKinley by his medical attendants. Sir Dyce Duckworth expresses the opinion that they were furnished with but slender regard to the decency and respect due to the privacy of the patient, and that many related to matters of treatment which were obviously unfit to be read, much less to be discussed, by the general public. He further speaks of the publication of such bulletins as a new departure and bad example afforded by America. We venture to think that Sir Dyce Duckworth is too severe in his condemnation and historically not quite correct. Everyone must allow that not only was President McKinley, as the Chief Magistrate of the United States, a patient of quite an exceptional position, but its tragic circumstances made the illness of especial interest, while there was an intense and not unnatural desire on the part of the public to be kept accurately informed of the progress of the patient. It is reasonable to make allowances for these circumstances and to recognize, that details were justifiable in this case which would ordinarily be withheld. Moreover, is it correct to say that this practice of publishing details

of the illnesses of great persons was unknown a few years ago? We possess a letter written in 1891 by an eminent surgeon (now deceased) to Queen Victoria, a man of long experience and ripe judgment, in which, referring to the subject of medical bulletins, he wrote that such statements have always been published by those "who have been in attendance on members of the Royal Family during serious illness. This custom has been observed longer than anyone living can remember, and its maintenance is not dependent on those by whom these bulletins are signed." We have referred to the *Times* for 1830, about the time of the death of George IV, and find that daily bulletins were published and signed by Sir Henry Hallford and Sir Matthew Tierney, and that after the King's death fuller details of the illness were given in the obituary notice. While we share the objection to signed medical bulletins, and the appearance in the newspapers of details from the sick rooms of citizens of more or less public importance, we think it must be held that rulers of States and members of reigning families constitute exceptions. It is quite possible that Sir Dyce Duckworth had in his mind particular passages which erred in point of taste, but, speaking generally and from recollection of the official bulletins, we do not think that the physicians and surgeons in attendance upon President McKinley published anything that was unworthy of the medical profession.

Correspondence.

MOSQUITOES AND YELLOW FEVER.

By JOHN H. PURNELL, M. D., Vicksburg, Miss.

To the Editor of the *Philadelphia Medical Journal*:

In your issue of August 24th is noted the very able criticism of my article by Assistant Surgeon Bispham. It is gratifying to see that interest is manifested in yellow fever, a subject of such great importance to the people of our country, especially to those of the South Atlantic and Gulf States. In discussions and investigation of yellow fever, its causation, and conveyance, only the desire for truth should actuate our efforts, and no one should welcome the discovery of an error more heartily than he who makes it.

Dr. Bispham's criticism covers my article pretty thoroughly, but not entirely. The paragraph in it touching the primary infection is not alluded to. This seems to me of vital importance. The Army Commission says that the insect is infected solely by stinging an individual suffering with yellow fever, and since yellow fever infection does not belong physiologically to the human economy, then the human supply must have been obtained from some extraneous source, and that independent of the mosquito. In the consideration of the instances of recrudescence the most typical illustration it not alluded to—that of the recurrence of Yellow fever on board of the U. S. S. S. "Plymouth," in 1879. This is one of the greatest moments since absolute data concerning it are obtainable. To those not familiar with it, a brief recital will be of interest. The Surgeon General of the Navy furnished the following account of the case of J. M. Keating, in 1879: "On Nov. 7, 1878, four cases of yellow fever occurred on board the vessel while lying in the harbor of Santa Cruz. These were removed to the hospital on shore, and the ship sailed to Norfolk. Three mild cases occurred during the voyage, and the 'Plymouth' was ordered to Portsmouth, N. H., thence to Boston. At the latter port everything was removed from the ship, and all parts of the interior freely exposed to a temperature which frequently fell below zero, exposure continuing for more than a month. During this time the water in the tanks, bilges, and in vessels placed in the store room, was frozen. One hundred pounds of sulphur were burned below decks, this fumigation continued for two days, and the berths, decks, holds and store rooms were thoroughly whitewashed. On March 15, (1879) the ship sailed from Boston southward; on the 19th during a severe gale, the hatches had to be battened down, and the berth deck became very close and damp. On the 23d

two men showed decided symptoms of yellow fever, and on the recommendation of the Surgeon, the vessel was headed northward. The sick men were isolated, and measures adopted for improving the hygienic condition of the vessel and crew. The Surgeon reported that he believed the infection to be confined to the hull of the ship, especially to the unsound wood about the berth-deck, all the cases but one having occurred within a limited area; and that, while the "Plymouth" is in good sanitary condition for service in temperate climates, should she be sent to a tropical station, probably no precautionary measures whatever would avail to prevent an outbreak of yellow fever."

Many of the data are complained of as being incomplete. That is so, and from the nature of things could not be otherwise. Until a few months ago no one save Dr. Finlay had suggested the mosquito as being connected with yellow fever propagation, and the theory of fomites conveyance prevailed for years.

During the prevalence of an epidemic, especially after it had been well established, physicians devoted their energies to the relief of the conditions rather than to the discovery of the cause. Occasionally, an outbreak of yellow fever followed the introduction of material from an infected center, and the incident was reported as an item of interest and curiosity, rather than as evidence to support a theory which was already accepted, hence explicit data were not chronicled at the time, and therefore are not obtainable. In using such material, I stated that it emanated from medical men who recited the cases as occurring under their observation, and as such should receive consideration.

In criticising the illustrative cases of long retained infection occurring on vessels, Dr. Bispham suggestively attributes the development of cases to the sting of mosquitoes, and supports his position by citing several instances of long lived insects, notably one of Dr. Reed's mosquitoes which lived for 71 days, and several reported by Mr. Le Prince, which lived up to 70 days. Concluding he says: "On this reservation I have also observed some mosquitoes living 60 days after *all breeding places* have been destroyed. This last was particularly suggestive, as the insects were living in the *open* where they could be preyed upon by their numerous enemies."

This statement concerning the longevity of the insect in the open is interesting and instructive, not only in that knowledge is acquired concerning the mosquito's life cycle, but in illustrating how delicately discriminating an investigator's acumen may be perfected. The recognition of individual "stegomyia" as they fly about the reservation, unmolested, save by their natural enemies, for a period of two months is indicative of powers of discernment most wonderfully developed. Dr. Reed's 71 day mosquito had not gained publicity when my paper was completed. Since the fact is known I will modify my statement by saying "the life of the mosquito, under *ordinary* conditions, has not been determined." Professor Geo. E. Beyer, of New Orleans, in a paper read before the "Louisiana State Medical Society," on April 19th, says: "In no instance, however, was I able to lengthen the life of a female beyond a period of 22 days. In all experiments I resorted to all kinds of methods to test the longevity of the insects." And again he says, "How other investigators should have succeeded to keep mosquitoes on 'various substances' for a month, and longer, is inexplicable to me."

In considering the case of long retained infection on vessels, occurring 39, 56, 64 and 68 days after departure from an infected port, it is unreasonable to attribute the development of yellow fever cases to an insect's sting. Entomologists claim that in order to exist, mosquitoes must have water—being deprived of it they can not live more than five or six days. Where water is accessible on ship-board, an opportunity for satiating her sanguinary desire is afforded the female "stegomyia," and since it is presumed the power to infect or not infect at pleasure is not possessed by mosquitoes, it is a most reasonable presumption that cases of fever would occur days before the destination is reached.

Concerning my reference to the great number of cases of fever occurring in 1878, and at Edwards in 1897, Dr. Bispham says: "He ends the paragraph by this sentence, 'Is it reasonable to suppose it was accomplished by the mosquito?'"

That paragraph should have been taken in connection with the one just preceding it, concerning the cases occurring in Edwards which reads: "Is it reasonable to suppose that each case was the result of a sting delivered by a mosquito who had stung a case of yellow fever twelve days previously?"

That is not particularly absurd. Consider the cases of malarial fever, the propagation of which, it is claimed, is dependent upon the sting of the "anopheles" that develops its power to infect seven or eight days after its bite.

Compare the number of cases developing during the same season that yellow fever prevails, with the number occurring of the latter disease, and see if some other agent than the mosquito is not responsible. In a report made to the "British Medical Association," at its last session, it was claimed that "about 70% of mosquitoes fed on malarial persons became infected, and seven out of the eight persons bitten by these mosquitoes had the fever."

Not much greater percentages of infected "stegomyia" have been reported, nor has its power of imparting infection greatly exceeded the "anopheles," while the period of developing the poison is four or five days shorter in the latter than in the former. Why then should the former be charged with cases of infection so very largely in excess to those attributed to the latter?

In order to show that mosquitoes existed in sufficient numbers to cause the epidemics, Dr. Bispham says: "Howard observed that 19,110 mosquitoes were counted in one barrel." This is an error. Dr. Howard observed that 19,110 eggs—larvae, and pupae—no mosquitoes—were counted." How many different kinds or how many would have merged into imagoes was not stated. It is agreed, however, that mosquitoes are sufficiently plentiful for all purposes, but they are *not infected*, and it is necessary for them to wait twelve days after biting a yellow fever case before they become dangerous. Many perils beset the life of a mosquito—besides, inhabitants of mosquito districts devise all kinds of ways and means for protection against the insect; it is therefore safe to assume that only a limited few of the female "stegomyia" succeed, at the termination of their twelve days probation, in imparting their poison.

In the characterization of my statement—"It can scarcely be conceived that the mosquito could harbor the germ for such a time," (from one season to another) "as a lack of information on the subject," Dr. Bispham displays his inability to grasp the full meaning of the statement. Every one knows, who has lived in a mosquito infected country, and who has given the matter any thought, that insects must necessarily hibernate if they are to be perpetuated; and while mosquitoes disappear with the approach of cold weather, they re-appear with the advent of the balmy spring days. In this climate they forsake their winter homes about the middle of April, so stated by Prof. Beyer, of New Orleans.

The two occurrences of a recrudescence of yellow fever related in my paper took place in the summer and fall, in Memphis, July 9th, 1879, and in Edwards, September 1st, 1897. Consider, if you can, a hungry "stegomyia" curbing her appetite from three to five months while ample opportunity for indulging it is constantly afforded. If cases of yellow fever are dependent upon the mosquitoes' bite, where a recrudescence is noted (and we would have recrudescences very much oftener than they have been, if they are so dependent) the first cases would develop two weeks after the advent of the mosquito, for the hungry "stegomyia" searches for blood, and will overcome many obstacles to get it. If infection is derived from fomites, cases would not occur until warm weather is thoroughly established, and not then unless accidentally disturbed.

Note the two sources of infection again: the one, very

active, searches for the victim—the other remains perfectly quiescent until accidentally disturbed. Which is the most reasonable source? In accounting for the absence of yellow fever in Camp "Joe Williams," in 1878 he says: "The reason of all this is that what few mosquitoes might be taken to the camp in the first place can find no suitable place to breed, as very little water is allowed to stand in cans about the ground, on account of the usual trouble in obtaining it, and therefore they are soon killed." In the selections of sites for camps, the water supply is the main object and no place without a good supply would have been selected, and with more than a thousand people congregated together, a few cans would have been discovered by the little insects, and since "one little can" can "raise enough to make it extremely unpleasant for one to approach within a hundred yards of it," two or three little cans could raise enough to spread yellow fever. Breeding places, however, are unnecessary, for a recent observer states: "On this reservation I have also observed some mosquitoes living nearly *sixty days after all breeding places have been destroyed.*"

Continuing, Dr. Bispham says, "Further on he mentions the fact that there are many mosquitoes in and about Memphis, but he does not remember that recent investigations have proven that the *Culex* almost always breeds in artificial collections of water, which are more usually found about houses, and the variety of mosquito inhabiting the country districts is likely to be *Anopheles* or some other not *Culex*." The foregoing argument can only be justified by the acknowledgment of lack of information concerning the wide-spread prevalence of yellow fever in the rural districts in 1878. The conditions which prevailed at Orrwood and Taylor, Miss., 75 miles below Memphis, in 1898, should have suggested to my critic that if the "steptomysia" is solely responsible for yellow fever propagation, there is no place too obscure for them to breed and thrive. In 1878 when the disease was introduced into a rural district, and no isolation precautions taken, its spread was similar to that in cities and towns.

The epidemic at "Orrwood and Taylor" was strictly a rural one. The houses were from three to twelve miles apart, and the origin of nearly every case could be traced to an infected house, or to material that had been exposed.

In commenting on the Edwards epidemic, he says: "In these accounts he does not give a complete enough elimination of all other chances of exposures to the infection. This lack of complete history is very noticeable, etc." The history of that epidemic was complete and was related as it occurred. No attempt has been made to support a theory at the expense of facts. That there was nothing more to relate concerning the outbreak of fever at Edwards, is not the writer's fault, it just occurred that way, and the writer chronicled the happening. That secondary cases should have occurred 11 and 12 days after the first possible exposure, was another fact that "simply happened." In this connection I wish to suggest that for the purpose of fair comparison of secondary cases occurring from suspected fomites, with those produced by mosquito bites, there should be three days deduction made in the fomites cases for the period of incubation. This has not been *done* heretofore except in my article.

In conclusion No. 3, the Commission, did not dogmatically state that 12 days must elapse, but it is inferentially so stated. They say—"An interval of *about 12 days—or more*, after contamination, appears to be necessary before the mosquito is capable of conveying the infection."

Conclusion No. 4 says: The bite of the mosquito at an earlier period after contamination does not appear to confer any immunity against a subsequent attack." Dr. L. O. Howard in his valuable book on the mosquito, seems to have construed these conclusions as I did, for he says, " * * * and Doctors Reed, Carroll and Agramante have demonstrated that the yellow fever mosquito

will not convey the disease until at least *twelve days* have elapsed since the time when it bit a yellow fever patient."

In commenting on the recurrence of cases of fever which were suggested as originating from fomites, the Doctor asks "Why could not infected mosquitoes remain in the house for that length of time, when they have been observed to live for 70 days? Other cases brought up in the same way can be dismissed with the same query." They can be so dismissed if one is not looking for facts concerning the subject, but while there remains any doubt as to the mosquito's sole responsibility in the premises, the true scientist and sanitarian will weigh each phase of the question well before reaching his conclusions. Continuing the Doctor says:

"Finally he makes the statement: 'Among the many sanitary measures adopted looking to the control of yellow fever epidemics and to the complete eradication of the disease, no exertions were ever directed toward the mosquito extermination.' That is a great mistake, for from time immemorial, sulphur has been used as a disinfectant * * * On investigation it has been found that sulphur destroys mosquitoes, etc." The quotation from my paper is correct, no measures directed to the mosquito extermination were ever adopted before. The comment, however, is quite ludicrous. If a few birds were killed during the Santiago engagement, would the report have gone in to Washington that "The boys went bird hunting this morning?" If a few mosquitoes were killed during sulphur fumigation, it was only an incident in the disinfection. The halls, kitchen and unoccupied rooms as a general thing were not subjected to disinfection, and no oil was ever poured on the breeding places.

In conclusion, Dr. Bispham "takes the liberty to call my attention to the fact that very many epidemics are spread by mild cases which are unsuspected and therefore unprotected." With as much propriety, as far as conveying information is concerned, the Doctor might have said "the sun shines!" If he had been actively engaged in the yellow fever field during the past five years, he would have known that it was the mildness of the disease which has been the cause of the greatest confusion. In some localities it was so mild that the name "Yellowoid" was suggested, that it might be distinguished from the type of fever of Seventy-eight. Look over the epidemics of the past and note the mortality attending the disease. It will be seen that the percentage of deaths ranges from four per cent. in the Brownsville, Texas epidemic (Murray) to 33 1/3% in 1878. No matter how mild the disease is, it is usually accompanied by a mortality sufficiently great to cast a gloom over any community it may visit, and he who discovers its cause and suggests measures for its control, will prove himself as a benefactor indeed. To that end we should all strive, adhering to no single theory, until facts are established susceptible of absolute and uncontrovertible demonstration.

Scoliosis and Rachitis.—In the *Bulletin Medical*, (June 15, 1901, No. 47), Dr. H. Mayet discusses rachitic scoliosis. Out of 152 cases seen at the Hôpital des Enfants Malades, all but 10 were due to rickets, or were called essential, appearing during adolescence. The causes of the other 10 cases were varied and definite. Lannelongue believes that the cause in most cases is rachitis. In the majority of cases the scoliosis developed between the sixth and ninth years. Nowadays the muscle theory, the ligamentous theory, and the osseous or physiological theory have all been abandoned. The cause of scoliosis in adolescents seems to be habitual position. Mayet examined 25 cases, of different ages, and found that in 8 of them the scoliosis developed after a long illness. All showed the signs of previous rickets. Besides, out of 220 rachitic infants, 217 showed scoliosis upon examination. Mayet concludes that rachitis is the underlying cause of essential scoliosis. Rest on the back is the best treatment, the signs of rickets disappearing as the scoliosis grows less marked. Professor Lannelongue has perfected an apparatus, soon to be fully described, for measuring the scoliosis. [M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Pathological Society of Philadelphia.—At the last meeting of the Pathological Society, held October 10, the following officers were elected for the ensuing year: President, Dr. Charles W. Burr; vice-presidents, Drs. Simon Flexner, Alfred Stengel, and Joseph McFarland; secretary, Dr. J. Dutton Steele; treasurer, Dr. T. S. Westcott; recorder, Dr. David Hlesman, and curator, Dr. W. W. Babcock.

Wills Eye Hospital.—Dr. William F. Norris has resigned his position as attending surgeon at the Wills Eye Hospital after a service of almost thirty years. He will become a consulting surgeon of the institution. Dr. William Zenlmayer has been appointed his successor. Dr. George C. Harlan has also been appointed consulting surgeon, while Dr. Paul J. Pontius was made assistant surgeon to Dr. S. L. Ziegler.

Society Meetings of the Week.—The following societies hold their meetings next week at the College of Physicians, at 8 15 P. M.: Wednesday, October 23, Philadelphia County Medical Society; Thursday, October 24, Pathological Society.

A Future Bequest.—Only upon the death of Mrs. Elkinton will the bequest of \$25,000, \$5000 to the orthopedic dispensaries of the University of Pennsylvania, Jefferson, Orthopedic, Polyclinic, and Pennsylvania Hospitals, each, left by the late Thomas Elkinton, become available.

McKinley Memorial Hospital.—The new hospital for contagious diseases, for which funds have for some time been collected, will be known as the McKinley Memorial Hospital. In order to further increase this fund a Meschlanza will be held in the Academy of Music, November 11th to 16th. There will be a bazaar in the foyer of the Academy, presided over by well known young society women, while the patronesses, who number nearly 1000, will take charge of three monster euchre parties, to be held in the mornings. There is to be a University Night, when the Mask and Wig Club will present scenes from their various productions. Other features of the week will be a children's vaudeville, a children's colonial tea party, opera and drama by society amateurs of this city, and an afternoon with "Hugh Wynne."

The Smallpox in Philadelphia.—During the week ending October 12th, 60 new cases of smallpox have been reported in Philadelphia, a marked increase as compared with 29 and 40 for the two previous weeks. There were, however, only 2 deaths. Cases have even been found in Manayunk and Camden, and there are almost 150 cases in the Municipal Hospital. The disease prevails in nearly every section of the city, in spite of the efforts of the city authorities to check its spread. There are only three wards in the city that have no contagious diseases. They are the Fourteenth, Twelfth and Thirty-fifth wards. The Fourteenth and Twelfth are in the heart of the city. The Thirty-fifth embraces part of Frankford, Wissinoming, Somerton and other northeastern suburbs. The Bureau of Health has deemed it advisable to suspend its rule requiring the removal of all cases of smallpox to the Municipal Hospital. This rule was at first enforced because the outbreak was confined to colored settlements. But the disease now prevails among all classes, and in all sections and where infected persons have the money and facilities for the proper treatment of the disease at their own homes, they are permitted to remain. The smallpox epidemic now existing in London resembles this, in that it was at first circumscribed to one district of the city, that of St. Pancras, but cases are now reported all over London. The Director General of the Canadian Public Health has advised general vaccination throughout Canada, since 30,000 cases of smallpox have been reported in the United States from January to July.

Society Reports.—At the Philadelphia Academy of Surgery meeting held Monday evening, October 7th, Dr. Robert G. Le Conte read a paper entitled, "Gun-Shot Wounds of the Abdomen," reporting a case. The patient, 15 minutes before admission to the hospital, was shot twice with a 32 caliber revolver, one shot taking effect in the thigh, the second in the back. The patient was in a highly excited condition, complaining of cramp-like pains in the abdomen. Shock was moderate, respiration labored. The en-

trance wound was on a level with the crest of the ilium, 2½ inches to the right of the 5th lumbar spine. The abdomen was tympanitic and very tender. The wound was inspected, and a drainage tube inserted. Upon opening the abdomen, it was seen that the bullet had perforated the small intestine and the upper portion of the mesentery, severing one of the large vessels. The wounds were closed, the abdominal cavity being washed out with normal salt solution. It was thought that the bullet had lodged in the anterior abdominal wall. The patient recovered and was exhibited. Dr. Le Conte called attention to the question of interference, as he thinks that the abdomen should be opened in all penetrating gunshot wounds of the abdomen. Shock is invariably associated with hemorrhage and demands immediate interference. The abdomen must be opened to make a thorough examination. When there is a penetrating wound he makes his incision in the median or semilunar line; following the course of the bullet may leave a hernia. He treats the track of the bullet as aseptic until it proves itself otherwise. He considers it important to disinfect thoroughly the skin of the patient before opening the abdomen.

Dr. Richard H. Harte reported a case of **Gun-Shot Wound of the Abdomen** occurring in a young man of 19, who was accidentally shot in the abdomen along the right edge of the rectus muscle, about 1½ inches above the umbilical line. The abdomen was tender and rigid. A probe could not enter far. The abdomen was opened in the line of the wound, when considerable hemorrhage was noted. After a careful cleansing it was found that the bullet had pierced the upper part of the duodenum, which was closed with a single row of interrupted sutures and Lambert sutures. There was a large hematoma in the mesentery which was evacuated. After cleaning the cavity, the wound was closed. An incision was then made in the back exposing the uninjured kidney and another large hematoma which was cleaned out, the wound then being closed. The patient recovered. Dr. Harte advises exploring the abdomen in such cases. No attempt was made to locate the bullet, which should not be disturbed unless it gives rise to symptoms demanding its removal. These papers were discussed by Drs. Rodman and Hearn. Dr. Rodman stated that bullets of slow velocity frequently carry foreign bodies with them, such as fragments of clothing, and should not be treated as aseptic, but as septic wounds. He thinks drainage should practically always be employed and advises prompt operation. Dr. Hearn believes that gun-shot wounds of the abdomen should be operated immediately, and advises the use of drainage. Dr. Geo. G. Ross reported a case of **Intra- and Retro-Peritoneal Hemorrhage and Traumatic Rupture of the Meso-Sigmoid.** Upon opening the abdomen free blood was found in the peritoneal cavity. The abdomen was washed out with normal salt solution. The outer layer of the meso-sigmoid was denuded, the serous coat of the mesentery being sutured with fine silk. Six days later he was readmitted suffering from intestinal obstruction. He died after operation with purulent peritonitis. Dr. Ross also reported a case of **Compound Fracture of the Anterior Fossa of the Skull with Hemorrhage from the Nose, Ear, and External Wound.** The case history was given in full.

The Philadelphia Pediatric Society met on Tuesday evening, October 8, at 8.30 P. M. Dr. J. P. Crozer Griffith made a report for the Milk Commission of the Society. He said that the Society's certified milk was now in general use throughout the city. Dr. Alfred Hand, Jr. then presented a cretinoid boy of three and a quarter years, the fifth child of healthy parents. The child cannot walk, and can only say a few words. He shows good physical development, his expression is somewhat idiotic, the eyes are deep set, there is much dribbling of saliva, the tongue protrudes somewhat, the hands are small and paddle-shaped, and the abdomen is prominent. Thyroid extract was only given for a week, as the parents did not return because the

medicine was too expensive. Dr. Hand says that cretins seem immune to the infectious diseases until placed upon thyroid treatment. Then they seem very susceptible to them, often dying with measles or pertussis. Dr. J. Dutton Steele reported a similar case, and Dr. Maurice Ostheimer mentioned having seen two such cases in the past six months. Dr. Griffith stated that good effects follow the use of thyroid extract in most cases of stunted growth, without reference to athyroidism. Dr. J. H. McKee then read an able and entertaining paper upon the "Training of the Senses," in which he reviewed the growth of the child, the appearance of the first separate sensations, etc., with details and many interesting illustrations. He noted the medical aspect of the sensations through childhood, and advised that children be sent to school later, that they be taught to observe more, and that their early life be spent in the country, taking in impressions. This paper was discussed by Dr. Griffith, who agreed with most of the views held by Dr. McKee.

Vital Statistics of Philadelphia for the week ending October 12, 1901.

Total mortality	404.	
	Cases.	Deaths.
Inflammation of the appendix 1, brain 17, bronchi 2, kidneys 19, liver 4, lungs 28, pericardium 1, peritoneum 7, pleura 1, stomach and bowels 17, spleen 1,.....		98
Marasmus 19, inanition 14, debility 7		40
Tuberculosis of the lungs		51
Apoplexy 16, paralysis 7		23
Heart-disease of 29, dropsy of 1, fat- ty degeneration of 7, neuralgia of 2		39
Uremia 16, Bright's disease 2, dia- betes 1		19
Carcinoma of the face 2, breast 2, stomach 8, uterus 3, liver 3 ..		18
Convulsions 9, convulsions, puerper- al 2		11
Diphtheria	74	15
Brain-disease of 3, softening of 2 ..		5
Typhoid fever	80	10
Old age		10
Scarlet fever	49	1
Smallpox	60	2
Abscess, liver 1, alcoholism 2, asth- ma 1, anemia 1, burns and scalds 1, casualties 9, cholera in- fantum 1, cholera morbus 1, cir- rhosis of the liver 3, croup, mem- branous 3, drowned 1, dropsy, abdominal 1, dysentery 2, epilepsy 1, erysipelas 1, fever, malarial 1, gangrene, foot 1, hanging, ac- cording to law 2, hemor- rhage 1, hernia 1, indigestion 2, jaundice 1, measles 1, obstruction of the bowels 3, rheu- matism 1, sarcoma, femur 1, scler- osis, arterial 1, shock, surgical 1, septicemia 5, suicide 4, tumor, ab- dominal 1, ulceration of the stom- ach 2, unknown coroner case 1, whooping cough 3		62

NEW YORK AND NEW JERSEY.

Rockefeller Institute for Medical Research.—A tentative working plan has been adopted by the officers of the Institute for Medical Research, founded by John D. Rockefeller, by whom it was endowed with \$200,000. It is to expend \$20,000 a year, divided so as to provide for forty scholarships; to make appointments for one year; to have candidates recommended by heads of various laboratories to the Board of Directors; to choose only persons pursuing, or about to pursue, investigations on some important subject in pathology, bacteriology or hygiene. At the time the announcement was made that Mr. Rockefeller had given \$200,000 to found the institute, it was said that the first

thing the institute would do, would be to investigate the milk supply of the city in co-operation with the Board of Health. This task was completed some time ago. It was also that work of a more ambitious nature, involving original research and an effort to throw new light on problems which are as yet unsolved by medical science, will be taken up in the autumn. The Board of Directors, which is assisting and directing these investigators in their work, comprises Dr. William S. Welch, professor of pathology, Johns Hopkins University, president; Dr. T. Mitchell Prudden, professor of pathology, Columbia University, vice-president; Dr. L. Emmett Holt, clinical professor of diseases of children, Columbia University, secretary; Dr. C. A. Herter, professor of pathological chemistry, University and Bellevue Hospital Medical College, treasurer; Dr. Theobald Smith, professor of comparative pathology, Harvard; Dr. Simon Flexner, professor of pathology, University of Pennsylvania; and Dr. H. M. Biggs, director of the laboratories of the Board of Health.—*New York Tribune*.

Columbia University Medical School.—An anonymous gift of \$25,000 is announced by the chancellor of the University of New York for the Medical School. W. F. Havemeyer has paid the bills for the improvements in the Havemeyer Laboratory.

Medical Directory of New York, New Jersey and Connecticut.—From the Medical Directory of New York, New Jersey and Connecticut it is seen that New York State has 10,112 physicians; New Jersey, 1,472, and Connecticut 1060. Municipal and State health laws are given in full for each State, and a directory of the national medical societies, with lists of their officers, is appended. The summer residences of such physicians as have them are given in each instance. The volume contains a total list of 12,644 physicians, with brief professional data appended to each name. Of the physicians in Greater New York, according to this directory, 3,991 are in Manhattan and the Bronx.

Diphtheria in Bloomfield, N. J.—There are already eighteen cases of diphtheria reported in Bloomfield, N. J. The Board of Health has ordered the Brookside School closed, as most of the cases developed among children attending that school.

A New Cure for Consumption.—Dr. Wilfred G. Fralick, visiting surgeon to the Metropolitan Hospital and consulting surgeon to the Brooklyn Memorial Hospital, is at work perfecting a remedy which he believes will cure tuberculosis and other bacterial processes. Until he has satisfied himself that his fluid is perfect, Dr. Fralick does not intend to publish its composition. The solution is injected intravenously, and has already caused great improvement in a number of cases. Though he has only employed this formula for six weeks, he is simply overwhelmed by phthisical patients from all over the world. While all bacteria are destroyed by this means, Dr. Fralick states that the solution will not build up tissues which are already destroyed. He intends to study its limitations, dosage, and exact effect, believing that premature publication of a remedy does more harm than good.

The Medical Society of the State of New York.—The annual meeting of the New York State Medical Society will be held in Hosack Hall, New York Academy of Medicine, 17 West Forty-third street, October 21 to 24, 1901.

The Birth-rate of Greater New York.—The Health Department returns show that in the last quarter reported by the Board, there were 144 births of children of Bohemian parentage, of whom 143 were born in New York county and only one in Brooklyn. In the same period there were 187 births of children of Swedish parents, and of these 103 were in Brooklyn and only 84 in New York county. There were 1465 children born of Austrian parents in New York—Hungarians, Poles or Germans—and of these 1352 were born in New York county and only 112 in Brooklyn. The same disparity in favor of New York county is to be seen in the case of the children of Irish, Italian and Russian parentage. But the number of children born of Scotch parentage, as well as of Swiss, Danish, Norwegian and Finn parentage, is as large in Brooklyn as in New York county, and the children of Canadian parentage nearly as large. Brooklyn retains as a borough its distinction of having the largest number of births of children of American parentage. It is the most truly American of the five boroughs which constitute the present city of New York. Manhattan is the most cosmopolitan.

Virchow Anniversary Dinner in New York.—Over one hundred representative medical men sat down to dinner at Sherry's in New York last Saturday evening to commemorate the eightieth birthday of Dr. Rudolph Virchow. Following the dinner Drs. William Osler, W. H. Welch, Andrew H. Smith and A. Jacobi spoke.

Dr. William Osler, of Baltimore, spoke of Dr. Virchow as a scientist and an anthropologist. He said, that this night, eighty years ago, was a memorable night in that it gave birth to a genius. Both environment and birth were the attendants that accompanied genius and in these respects Virchow had been very fortunate. Coming under the influence of Johannes Müller early in his student days, he found in that teacher new, broad, and stimulating thoughts. Müller had found pathological science still struggling with the vague and mystical conceptions of disease, founded on theories that needed verification, and it was to his credit that he had brought back into the study of medicine the methods of the old Greek physicians of sixteen centuries ago. In the days of Galen, observation, study and analysis had been the tenets of the faith, and it had been Müller who had reintroduced these almost forgotten ideas into the study of pathology. Virchow's long list of investigations on matters archeological indicate that he was not a dilettante student of this science but an accomplished master. His was not the dabbling with skulls and relics but the patient and keen seekings of a skilled and well stored mind. He was an acknowledged authority in this recondite branch of knowledge. In hygiene he and Pettenkofer may claim to be the masters, and Berlin's excellent showing as a healthy city is due to his work and forethought.

Dr. G. M. Gould, of Philadelphia, then read a telegram to Dr. Virchow congratulating him on his birthday and sending greeting from his American friends and admirers.

Dr. William H. Welch spoke of Virchow as a pathologist. "To describe his work in this branch," he said, "one needs a genius as universal as that of Virchow himself. When Virchow was a student, the science of medicine was still struggling with the dogmas of a speculative age, but in the collateral sciences a great renaissance was taking place and Virchow was a worthy addition to that group of men who have made the sciences of chemistry and physics anew. One important factor in the estimation of his greatness and of his development was the fortunate choice of the subjects of his early investigations. The chemistry and morphology of the blood, then inflammation and then a study of connective tissues were the subjects of these early observations, and when their fundamental character is borne in mind, their influence on Virchow's mind and the growth of pathology may well be seen. His studies on emboli and thrombi mark an epoch in the study of pathology and in 1858, with the appearance of his Cellular Pathology, the foundation of modern pathology was laid. Morgagni had first showed the significance of organs, Bichat had directed attentions to tissues, but Virchow had shown the fundamental importance of the cell. His was the perfection of method as opposed to doctrine. Disease was life under changed conditions, and this primary and important conception made a great departure in the study of pathology and of medicine in general."

Dr. Andrew H. Smith then gave a number of charming personal reminiscences of his early student life with Virchow in 1858. He described the methods of conducting autopsies introduced by Virchow. Before his time the study of the dead body was most superficial and for the purpose only of ascertaining the name of the disease that caused death. With Virchow, however, the body was made to speak, and every organ made to give some information bearing on pathological truth. He also spoke of Virchow's efforts to cultivate a simple and straightforward style in his writings, in as much as he had been compelled in his student days to translate much that had been written by his teachers and immediate predecessors. His personal relations were most interesting. Virchow was a very democratic and approachable man, and gave to his students much of his time.

Dr. A. Jacobi then spoke of Virchow as a citizen. A pleasing feature of the dinner was the well devised menu for which Dr. E. L. Dana was largely responsible. It represented a facsimile copy of Virchow's "*Archiv für Pathologische Anatomie*," preserving its characteristic green cover, and contained two portraits of Virchow, at 38 and at 78,

a list of his more important contributions to science—and the menu proper.

The Report of the Milk Commission of the New York County Medical Society, which is treated editorially in this issue, gives the results of over 800 separate bacteriological examinations of milk. Suggestions were made, during 39 visits to dairies, concerning cleanliness, rapid cooling, and packing in ice for shipment, with the result that the bacteria markedly decreased in number. Eight dealers have reached the standard set by the Commission (under 2% acidity and 30,000 germs to the c.c., and over 3.5% fat), and are now selling certified milk in New York.

Isolation Hospital, Newark, N. J.—The Common Council of the city of Newark has contributed \$20,000 for the construction of a new isolation hospital.

MISCELLANY.

Baths in the Public Schools.—From Boston comes the news that the six new public schools now being constructed will contain bath-rooms for the use of the pupils.

The Latest Population Statistics.—The Census Bureau issued a bulletin October 11th showing the population of the United States by sex, general nativity and color, for 1900. Of the total population of the United States, there were 39,059,242 males and 37,244,145 females. The native element numbered 65,843,302, and the foreign born 10,460,085. Of the colored population there was a total of 9,319,585, divided as follows: Colored, 8,840,789; Chinese, 119,050; Japanese, 85,986; and Indians, taxed, 137,242, untaxed, 129,519. There has been practically no change in the proportions of the sexes since 1890. The foreign-born element has increased since 1890 only 12.4 per cent. of its former number, as against 22.5 per cent. in the native-born gain. There has been a slight decrease during the past ten years of persons of colored descent, the proportion now being 11.6 per cent. In 1890 it was 11.9 per cent. The Chinese show a loss, and the Indians have decreased 2.5 per cent. In the United States proper, the largest proportion of foreign-born is found in North Dakota, where this element comprises 35.4 per cent. of the total population; the next largest percentages of foreign-born being found in Rhode Island, with 31.4 per cent.; Massachusetts with 28.9, and Minnesota, Montana, Connecticut and New York, with about 26 per cent. each. The native Indians of Alaska number 29,536, a gain of 16.5 per cent. since 1890.

The Fifth International Congress of Criminal Anthropology, at its meeting in Amsterdam, September 9-14, 1901, passed the following resolutions: "The members of the Fifth International Congress of Anthropology are in favor of the establishment of psycho-physical laboratories for the practical application of physiological psychology to sociological, abnormal, or pathological data, especially such as are found in institutions for the criminal, pauper, and defective classes, in hospitals, schools, and other institutions." This resolution has been passed in America by the American Medical Association, Association of American Editors, American Medico-Physiological Association, Association for the Study and Cure of Inebriety, the State Medical Societies of Connecticut, Indiana, Kansas, Kentucky, Louisiana, Minnesota, North Dakota, New Jersey, Pennsylvania, Texas and Wisconsin, the Mississippi Valley Medical Association, and the Medical Societies of the cities of St. Louis, Chicago, and Syracuse.

The Plague at Rio de Janeiro.—On Sunday, September 29, there were reported five cases and one death of plague at Rio de Janeiro, Brazil. Since then there have been reported about four new cases daily, making almost one hundred cases of bubonic plague in Rio.

Tubercle Bacilli in Cigars.—Dr. Klemperer of Berlin, who has found tubercle bacilli in cigars which had been manufactured by cigar-makers at their homes, advises smokers to use cigar-holders.

Obituary.—Dr. George W. Christian, at Austin, Tex., October 7.—Dr. J. A. W. Hetrick, at Asbury Park, N. J., October 9, aged 56 years.—Dr. John B. Everhart, at West Chester, Pa., October 8, aged 75 years.—Dr. Windsor P. Stoddard, at Manassas, Va., October 13.—Dr. C. L. Gross, at Pen Argyll, Pa., October 9, aged 65 years.—Dr. Landes, at Albemarle county, Va., October 9.—Dr. R. H. Burke, San Jose, Cal., October 3.

The Death of Dr. Moncorvo, the well-known pediatricist, of Rio de Janeiro, is announced.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended October 5th, 1901.

SMALLPOX—United States.

GREAT BRITAIN.

Smallpox in London.—The epidemic of smallpox in London, which was at first confined to the district of Saint Pancras, is slowly becoming diffused throughout London, from five to six cases being reported a day. A number of these cases are hemorrhagic in character. The spread of the disease is in many cases due to the return of the hop-pickers to London from Sussex. A recent examination of the school children in St. Marylebone showed that more than half of the children were unvaccinated. In spite of the harm done by those opposed to vaccination, who have been spreading anti-vaccination pamphlets through the city, many of the people of London are having their children vaccinated and are being revaccinated themselves.

Plague Suspect at Glasgow.—A Lascar suspected of being a sufferer from the plague was landed at Glasgow October 12th from the British steamer *Baravia* from Bombay. It is rather strange that a new case of plague should be discovered in Glasgow so soon after the report of last year's epidemic, which has just been published by Dr. A. K. Chalmers.

The Annual Medical Service at St. Paul's Cathedral, London, was held Thursday evening, October 17th. Many members of the medical profession attended the service in academical robes.

The West London Post-Graduate College.—The new buildings of the Post-Graduate College at the West London

Hospital were opened October 14th, when Sir William MacCormac delivered an address.

A Donation.—William Waldorf Astor has sent a check for \$50,000 to the Chairman of the National Society for the Prevention of Cruelty to Children, to form the nucleus of a fund for the acquisition of premises adequate for the transaction of this society's business.

Swansea Isolation Hospital.—It is proposed to erect a building containing four wards of twelve beds each and four two-bed wards, accommodating a total of 56 patients, in Swansea, which borough has a population of 94,000 people.

Dublin University.—The resignation is announced of Dr. Purser, King's professor of the Institutes of Medicine in the School of Physic, Trinity College, Dublin, who has filled that position for the past twenty-seven years. His successor will not be appointed until the beginning of the new year.

CONTINENTAL EUROPE.

The French Congress of Gynecology, Obstetrics and Pediatrics will hold its fourth annual meeting in September, 1902, at Rouen. Dr. Richelot has been elected president of the gynecological section, Dr. Guillemet of the obstetrical section, and Dr. Kirmisson of the section upon pediatrics.

Paris.—Dr. Jaccoud, professor of clinical medicine, and Dr. Panas, professor of ophthalmology in the University, have been elected honorary professors.

Physicians in French Politics.—42 members of the French Senate and 53 members of the Chamber of Deputies are physicians, making a total of 95 doctors in the French Parliament.

The Virchow Krankenhaus.—The new hospital, now in process of erection in Berlin, the most modern hospital in Germany, will be called the Virchow Krankenhaus, in honor of the noted pathologist who has recently celebrated his eightieth birthday. He was born on October 13, 1821, at Schivelbein, a small town in Pomerania. He was educated at a Gymnasium, in Berlin, and in 1839 he began his medical studies. He was graduated from the University of Berlin in 1843. The following year he was appointed assistant in pathological anatomy in that institution. In 1846 he was connected with the Charité Hospital, and a year later was appointed regular lecturer at the University. In 1848 he was commissioned by the Prussian Government to visit Upper Silesia to study typhus fever there. In 1849 he became professor of pathological anatomy at Würzburg, which position he held until 1856, when he was called to be Director of the Pathological Institute in Berlin. He was a member of the Prussian Chamber in 1862, and of the German Reichstag from 1880 to 1893.

Nineteen Physicians Quarantined.—About the middle of September the steamer *Senegal* left Marseilles upon a Mediterranean cruise. Among the 174 passengers were 19 physicians, some accompanied by their families. Before reaching Ajaccio, Corsica, their first stop, it was discovered that the second mate had bubonic plague. The steamer returned to Marseilles at once. A sailor was also found suffering from the plague. The passengers were kept in strict quarantine for ten days, while the steamer was rigidly disinfected. The mate died, but the sailor recovered. No other cases developed. Rats upon the steamer were killed and plague bacilli found upon them. The steamer had come from Constantinople. While the tourists complained of the poor food and service during their quarantine, they nevertheless continued upon their journey, leaving for Alexandria early in October.

Foreign Obituary.—Dr. Adolph Winter, professor of pharmacology at Leipzig, formerly librarian of the University, and publisher of *Schmidt's Jahrbucher*, died September 18th, aged 85 years.

Appointments.—Berlin: Dr. Frederick Phehn, lecturer on tropical hygiene in the Oriental Seminary, has been made professor. Halle: Dr. Ernst Ziemke has been appointed professor of medical jurisprudence. Stockholm: Dr. J. E. Johannsen has been appointed professor of physiology. Vienna: Dr. Theodor Escherich, professor of pediatrics at Graz, has been appointed professor of pediatrics at the University of Vienna, replacing the late Dr. Widerhofer. Marburg: Dr. Heinrich Bonhoff has been made professor of hygiene, making two professors of hygiene in Marburg, since Dr. Behring is already one.

1.—In the treatment of lupus by Finsen's light method, if the disease is so situated as to make accurate focussing impossible, the Roentgen rays prove of service. Morris has treated 36 cases of lupus vulgaris, 6 of lupus erythematosus, 14 of rodent ulcer, 2 of alopecia areata, 1 of keloid and 1 of epithelioma by Finsen's method. Of the cases of lupus 8 were cured and in 6 the result was unsuccessful or unsatisfactory. Seven cases of rodent ulcer were cured. In 2 cases of lupus erythematosus the result was satisfactory. The application of the light is followed by hyperemia and redness, followed by the formation of a bleb which, in about a week, breaks and dries into a thick yellow crust. Healing is complete in 10 days or a fortnight. The intensity of the reaction varies in proportion to the intensity of the light; according to the structural peculiarities of the patient's skin; and especially, according to the local conditions produced by the disease. The after-smarting is often considerable, and the inflammatory phenomena constituting the reaction are also more or less painful. The remedial effect of the light rays is directly proportionate to the intensity of the reaction. A coarse, thick skin, a large amount of pigment, deep seated disease, great thickening and infiltration of the tissues, large extent of the area involved, and cases in which mucous membranes are involved and the length of time over which the treatment has to be prolonged are the chief drawbacks of the method. Blacker found that with Finsen's rays reaction occurred in from 4 to 24 hours; with the X-rays in from 4 to 24 days. The first was comparatively slight and easily controlled; the second was sometimes severe, and an ulcer might be produced which would last for months. In the treatment of the pain accompanying ulceration he had found chlorotone and orthoform of service. Sequeira said that from an experience of 15 months work at the London Hospital, where there were 3 lamps continually in use and where nearly 200 patients had been under treatment, he had observed improvements in every case of lupus vulgaris of every degree of severity. He had treated 45 cases of rodent ulcer with the X-rays. The ulcer healed rapidly and huge cavities filled up in a remarkable manner. In the treatment of cancer by the X-rays he had found pain to be relieved and ulceration to be dried up, but in some cases the tumors grew rapidly in spite of the rays. A single case of nodulated leprosy of the skin had shown a marked improvement. In sycosis he had also obtained satisfactory results. Jamieson, from a limited experience, said that he believed that the Finsen light method and the X-rays were but additions to the armamentarium, to be had recourse to in special circumstances only, not indiscriminately. Walker thought one of the most satisfactory features was the success which attended the X-ray method in diseases that were extremely obstinate to other forms of treatment. He has seen good results in cases of lupus and in cases of sycosis. In lupus vulgaris, when the X-rays are applied to a moist surface, the discharge is lessened and assumes a purulent instead of a serous appearance. Normal epithelium develops very rapidly and healing quickly follows. When applied to dry surfaces exfoliation of the epidermis takes place, and the part exhibits a dried and shrunken appearance. Absorption of morbid products takes place, resulting in a smooth, soft and pliant scar. An erythema of uncertain duration always accompanies these changes, and unless this is permitted to disappear between each successive application of the rays, an aggravation of the disease occurs. Taylor referred to a case that illustrates the remarkable effect of the X-rays in stimulating the growth of the epithelium. Noiré and Sabouraud have treated 50 cases of alopecia areata by Finsen's light, but notwithstanding improvement in some cases, the results are not such as to lead them to substitute that method for the other methods of treatment already in vogue. Twenty cases of lupus vulgaris gave the following results: 5, in which the diseased area was of the size of a shilling, were completely cured by 5 exposures of one hour each at 4 days interval. In 12 other patients with extensive lupus, marked improvement was obtained, some portions of the diseased area being cured. As to lupus erythematosus, the results were disappointing. [J. M. S.]

3.—Arsenic eruptions due to the action of the vasomotor centers consist of more or less extensive diffuse erythematous eruptions, scarlatiniform, morbilliform or erythrodermic, in type of very unequal intensity in different parts but

usually preponderating on the trunk and upper limbs, especially in front. Phenomena due to the action of arsenic, on the nerve trunks include the flushing, the cyanosis and the edema so frequently observed on the face and extremities. These symptoms are non-inflammatory and are obviously due to vasomotor paresis. The nutritive group of arsenic eruptions comprise those changes that affect the normal growth of the skin apart from any inflammatory change, such as pigmentation, hyperkeratosis, erythromelalgia and hyperhidrosis. [J. M. S.]

4.—Roberts concludes that arsenic is not a drug possessing curative powers; that it is not necessarily an irritant poison; and that it is not a poison in itself, but that its action is irritated and determined by the tissues themselves. Its effects are essentially of a nutritive order, brought about by the agency of active oxygen. These effects are beneficial to the organism when the oxidation is slow, and injurious when too rapid. The more highly organized the cell, the more unstable its protoplasm, and the more rapid its metabolic processes, the more rapidly does it feel and manifest the action of arsenic. [J. M. S.]

5.—Crocker and Perret report the case of a man, aged 60 years, who was suffering from a small, painful sore, situated on the ulnar border of the right hand, close to the metacarpophalangeal joint of the little finger, and of 6 months duration. The patient had suffered from psoriasis at the age of 20, for which he had had arsenic, but he had not had any treatment for 38 years, and, so far as he knew, he had not taken arsenic since then. On the whole, the psoriasis had got better the last 2 to 3 years. The growth was excised in 1900. Later, there was marked induration on either side of the incision, but the skin was not involved and the growth was removed together with the little and the ring fingers. Histological examination showed the growth to be an epithelioma supervening on arsenical keratosis. [J. M. S.]

6.—Pratt reports a case of purpura hemorrhagica associated with general tuberculosis. [J. M. S.]

7.—In the treatment of advanced lupus Snow advocates scraping away as thoroughly as possible the soft cell growth, and then, as soon as bleeding has ceased, applying lint soaked in iodine liniment to the raw surfaces. The lint is removed on the following morning to prevent vesication. Then an emollient dressing is substituted. Notes of 10 cases are given. [J. M. S.]

8.—Hall reports a case of multiple disseminated lupus following measles; death from tuberculous meningitis. [J. M. S.]

9.—Marsh defines nasal obstruction as the inability to breathe freely and equably at the same time through both nostrils. Obstruction may be due to abnormal conditions of the turbinated bones and includes bone obstruction, soft tissue obstruction, and a combination of these conditions. Where turbinectomy is employed for bony enlargement, hemorrhage is often free, but is controlled by the application of, or tight packing with gauze dipped in solution of adrenalin chloride. Kelly said that one should be chary of treating the noses of medical men who are attending cases of influenza by operation. In several instances he has seen a severe attack of influenza follow cauterization in such a manner as to suggest a relation. Parker concludes (1) that even slight abnormalities occurring in the middle meatus are of more importance than great abnormalities in the inferior meatus, (2) that abnormalities causing obstruction between the middle and superior meatus are productive of harm, and may require treatment in order to restore the air way, (3) that in view of the fact that the inspired air does not pass directly over the inferior turbinate, it is probable that the mucous membrane covering the structure of the middle and upper passages shares the important function of warming and moistening the inspired air, (4) that operative interference should be strictly limited, no more of the parts being removed than is absolutely necessary to restore the natural air way, (5) that the inferior meatus is the natural channel for the drainage of the nose, and that removal of obstructing abnormalities is often necessary to render it efficient for this purpose. Thompson said that operative treatment should be most carefully avoided in cases exposed to influenzal infection; he had seen alarming symptoms undoubtedly caused by such infection. He could not agree that a patient was always better without a useless turbinate; but thought that it was better to have slight nasal obstruction than a freely pervious nose and pharyngitis sicca. Howell

spoke against the reckless removal of turbinates by some specialists, and was glad to find the Section of Laryngology and Otology endorsing this view. The operation is justifiable only when the needful air space is unobtainable by other means. [J. M. S.]

10.—Mackle finds that with very few exceptions, suppurative ethmoid cases are associated with polyp. He believes that we attach too much importance to dental mischief as the cause of cases of suppuration of the antrum and that the specific fevers, and more particularly influenza, are responsible for far more cases than diseased teeth. In the sphenoid cases, as a rule, he has been unable to fix a beginning or to trace a cause. If we have chronic discharge of pus from the nose, which persists after free drainage has been established by the removal of granulations, polyp, or bony obstructions, we must lay open the diseased parts in order to obtain a cure. In doing so, provided we keep in clear view the position of the brain and orbit, and provided, always, that we keep in the path of the pus, there can be only slight danger of accidents. In a long-standing case the hesitating and timid hand is not likely to meet with much success. [J. M. S.]

1.—Hemmeter discusses "the diagnosis of cancer of the stomach." The author states that at the present day we do not understand the nature of carcinoma. No matter how we direct our measures of treatment or at what time they are begun, the individual will eventually suffer from the recurrence of the disease. This occurs in 99% of the cases of operated gastric cancer. An early diagnosis is the only one that is of interest to the surgeon. He considers seriatim the different clinical methods which are employed in the recognition of carcinoma of the stomach. In regard to age, he quotes the statistics of a number of authorities, who have found that gastric cancer occurs in three quarters of the cases between the ages of 40 and 70. A number of instances are on record in which cancer of the stomach occurred at a very early age, and for this reason he cautions the physician not to give undue importance to the question of age. Hemmeter believes that the limited age for carcinoma is gradually receding. In his experience, one half of the cases of gastric cancer presented bloody vomiting, the vomit, as a rule, assumed a characteristic "coffee ground appearance." Rarely are large quantities of blood vomited; nevertheless, in cases of gastric ulcer small hemorrhages may occur, while in gastric cancer large hemorrhages may occur, and he has observed cases of gastric ulcer showing coffee ground vomiting repeatedly. In 75% of the cases of cancer of the stomach he has observed constipation, while in 20% diarrhoea, and only in 5% were the stools regular. Emaciation and cachexia are by no means characteristic symptoms of gastric cancer, they are, nevertheless, important, because they influence the surgeon in his decision for operation. The high degree of emaciation and cachexia may result from a very small cancer, while at other times, a large growth is accompanied by a slight degree of emaciation and cachexia. In respect to the conditions of the gastric functions, he believes that there is sufficient evidence for the conclusion that the presence of hydrochloric acid by no means argues against cancer of the stomach, its absence cannot point against the existence of this condition. The presence or absence of hydrochloric acid, when considered with other symptoms, has some diagnostic signifi-

cance. A decrease in the secretion of rennin and pepsin is of little diagnostic value, as such a change may occur in other diseases. The presence of lactic acid should be regarded as a very important sign and should suggest gastric cancer. This cannot be regarded as an early sign. For clinical purposes he recommends Uffelmann's test for the detection of lactic acid. He highly advocates the use of the microscope for the detection of the Oppler-Boas bacillus, mitotic cells, or parts of the growth, in the stomach contents. The Oppler-Boas bacillus occurs in the stomach in a large percentage. This must be regarded as a late sign of the cases of gastric cancer. He has found curettage of the stomach, with a soft rubber tube, a valuable adjunct in diagnosis. By this method, which is practical, unaccompanied by danger, he has been able to detach some of the cellular elements. By staining these cells, important evidence is secured. The presence of karyokinetic figures should be regarded as an early sign. The determination of a reduction of the absorption power of the stomach, the presence of a large amount of indican in the urine, and the existence of blood changes, cannot be considered as signs possessing very little diagnostic value. He believes that the finding of a tumor is the most reliable evidence in establishing a diagnosis, but unfortunately this is a late manifestation, nor does it occur in all cases, and its existence does not point absolutely to a malignant growth. He thinks that the solution in the treatment of carcinoma of the stomach will not be found in a surgical operation, which at the present day offers most, but at best, only slight chances for recovery.

2.—Fenwick classifies syphilitic affections of the stomach into, (a) those due to the formation of gummata; (b) those due to the production of endarteritis; and (c), those due to the existence of chronic inflammation of its mucous membrane. The diagnosis of syphilitic gastritis, if there is any doubt as to its existence, may be cleared up by a few days' trial of iodide of potassium treatment. Non-syphilitic cases are aggravated by this treatment, while with specific cases the contrary result is obtained.

[F. J. K.]

3.—Rabinowitsch discusses "the infectiousness of the milk of tuberculous cows; the bacteriological diagnosis and the practical value of tuberculin for the extermination of tuberculosis among cattle." The author mentions that about 90% of the cases of tuberculosis in swine have originated from feeding with infected milk. Rabinowitsch found that tubercle bacilli may exist in the milk of animals suffering from latent tuberculosis, the condition being revealed by the tuberculin test. Intraperitoneal injections of milk containing tubercle bacilli into guinea pigs form the most satisfactory way of demonstrating the presence of infectious milk. Even very slightly infectious milk will give rise to tuberculosis by this method of experimentation. Previous observations have convinced the author that the detection of tubercle bacilli by means of microscopical examination is unreliable for the reason that the absence of acid resisting bacilli from the specimens examined cannot be considered convincing, as the number of bacteria may be very small, so that they cannot be demonstrated on every slide examined, and also for the reason that the acid-resisting bacteria have been found in milk, which are difficult to distinguish from tubercle bacilli. Acid-resisting bacteria other than tubercle bacilli have been found in specimens of mixed milk and also in milk taken under aseptic conditions from the individual cows in from 20 to 25% of the cases examined. The author therefore concludes that the only reliable method for demonstrating tubercle bacilli in milk is by animal experiments, namely, intraperitoneal injection into guinea pigs with a mixture of cream and sediment of thoroughly centrifuged milk. From a study of a number of cases the conclusion is arrived at, that the clinical diagnosis of tuberculosis, particularly tuberculosis of the udder, does not enable us to judge whether tubercle bacilli are secreted with the milk of the diseased animal; nevertheless, the presence of tubercle bacilli in the milk of diseased cows, suffering from tuberculous disease of the udder, depends largely on the extent of the disease in these organs. The recognition of bovine tuberculosis, with the view of its extermination, seems impossible without the aid of tuberculin.

[F. J. K.]

4.—Richmond reports a case of acute pneumonia, treated

with oxygen, occurring in a man 23 years of age, with recovery. [F. J. K.]

5.—Bellamy outlines a résumé of the modern views of gastric digestion. He points out that recently it has been shown that ethyl alcohol possesses the property of increasing the gastric secretion of pepsin, being therefore a true "succagogue." Indulin and glycogen possess the property of increasing pepsin without influencing gastric juice secretion, therefore being a true "pepsinogenes." We quote in substance a number of important practical hints: "(1) After a meal consisting of 'indifferent' food-stuffs, such as boiled and washed-out meat or coagulated albumin, 10 cubic centimetres of juice may be secreted by the stomach in one hour; these 10 cubic centimetres will barely digest one cubic centimetre of albumin. (2) After a similar meal to which has been added a juice expelling substance, 50 cubic centimetres of juice are secreted in one hour. A portion of 10 centimetres taken from this juice will digest one cubic centimetre of albumin; thus the whole hour's secretion digests five cubic centimetres instead of one. This is already a great advantage for digestion. (3) After a meal similar to No. 1, to which has been added a pepsinogenic substance, barely 10 cubic centimetres of juice are obtainable in one hour, but these 10 cubic centimetres digest, say, six cubic centimetres of albumin. This is also a great advantage for digestion. (4) Finally after a meal similar to No. 1, to which has been added both a juice-secreting substance and a pepsinogenic, 50 cubic centimetres of it can be collected in one hour, of which each 10 cubic centimetres digest from five to six cubic centimetres of albumin—i. e., in all from 25 to 30 cubic centimetres. Here the advantage is enormous, it being 25 to 30 times stronger than in the first case and from four to five times stronger than in the second and third cases."

[F. J. K.]

6.—Fisher reports a case of hemiplegia occurring in a girl 8 years of age, followed by aphasia and the appearance of a dilated superficial abdominal vein, suggesting thrombosis of the external iliac vein and thrombosis as a cause of the hemiplegia. [F. J. K.]

8.—Martin reports a case of pneumothorax shown by the Roentgen Rays. By this method he cleverly demonstrated the positions of the misplaced organs—heart and lungs, widening of the intercostal spaces and the presence of tubercles. [F. J. K.]

MEDICAL RECORD.

October 12, 1901.

1. Panhysterokolpectomy; a New Prolapsus Operation. GEORGE M. EDEBOHLS.
2. Strangulated Hernia in Infants. CHARLES N. DOWD.
3. A Study in Heredity; In its Relation to Immunity and Selective Activity in Tuberculosis.

HERBERT MAXON KING.

4. Epilepsy; Its Etiology and Treatment. J. L. BOWMAN.

1.—Edebohls remarks that the very multiplicity of operations heretofore proposed for the cure of prolapsus of the uterus and vagina is proof, if such were needed, that no operator of larger and longer experience is entirely and absolutely satisfied with the results of all his prolapsus operations. There is room, in the treatment of complete prolapse of the uterus and vagina, for an operation which, properly and successfully performed, will guarantee a certain and permanent cure of the prolapse. Such an operation is panhysterokolpectomy, the essentials of which consist in complete removal of the uterus and vagina followed by operative obliteration or columnization of the bed of the genital tract. The tubes and ovaries are not disturbed, if healthy; if diseased, they are removed with the uterus and vagina. Obliteration and columnization of the bed of the removed uterus and vagina is effected by means of from seven to nine buried pursing sutures of chromicized catgut placed about two to two and a half centimeters apart, and running parallel to each other. Each suture gathers the raw surfaces from the periphery in circular fashion and draws or purses them together in the median line. It is buried by being pushed upward toward the abdomen, while the next suture is being tied beneath it.

The effect of the completed operation is to build a solid pelvic floor ten to fifteen centimeters in depth from peritoneum to perineum, and to establish broad apposition of the base of the bladder and the anterior surface of the rectum, conditions similar to those obtaining in the male pelvis. The patient is kept in bed for a week after operation. Recurrence of prolapse is impossible after a correctly and successfully performed panhysterokolpectomy. The operation is indicated in the severest cases of total prolapse, and more especially where other operative procedures have been tried and failed. The interference with further marital relations must be explained, and accepted by the patient prior to operation. In the case of a married woman the husband must also be consulted. Four cases have thus far been operated upon by the author of the operation, all with perfectly satisfactory result. [W. A. N. D.]

2.—Charles N. Dowd presents a paper on **strangulated hernia in infants**, the reports of twenty-five operations in such cases in children under one year of age since May, 1898. There was only one death among the twenty-five cases. In addition, the one hundred cases previously tabulated by the author, indicate beyond all question that infants endure this operation very well. The report of a case is given in which the intestine had almost slipped back into the peritoneal cavity, leaving no palpable tumor, although the strangulation persisted. The operation was done on account of the symptoms and history. The child left the hospital on the eighth day. The records indicate that delay in interpreting the symptoms or reducing the hernia by taxis have been the greatest danger, while early operation has been the greatest safeguard. [T. L. C.]

3.—Herbert Maxon King reports a **study in heredity; in its relation to immunity and selective activity in tuberculosis**. He summarizes this paper by stating: (1) That the percentage of consumptives having a tuberculous parentage is actually smaller than that having a non-tuberculous parentage, and much smaller than would be more than accounted for by the additional risk of infection to which the former class is subjected. (2) Tuberculosis in the parents renders to no inconsiderable extent an immunity to the disease in the offspring, an immunity which of course is but relative, and not sufficiently protective, but still demonstrable, as is shown by the increased resistance to the progress of the disease and increased tendency to recover among the class. [T. L. C.]

4.—J. L. Bowman discusses **epilepsy; its etiology and treatment**. Speaking of treatment this writer believes that it can only be carried out in homes for epileptics, and he makes a plea for the extension of these institutions. [T. L. C.]

MEDICAL NEWS.

October 12, 1901. (Vol. LXXIX, No. 15).

1. The Endowment of Medicine. MALCOLM MORRIS.
2. The Influence of the Colorado Climate Upon Pulmonary Hemorrhages. S. G. BONNEY.
3. The Tuberculosis Question. H. ARROWSMITH.
4. The Prevalence and Treatment of Tuberculosis Among the Poor. H. L. FANCHER.
5. The Crowding of Consumptives Into the Municipal General Hospitals. WILLIAM RIDGELY STONE.
6. Tuberculous Otitis Media, Mastoiditis and Meningitis in an Otherwise Apparently Healthy Adult. Brief Report of a Case. JAMES FRANCIS McCAW.
2. S. G. Bonney concludes his article on the influence of the Colorado climate upon pulmonary hemorrhages as follows: (1) That hemorrhage by itself, save with few exceptions, furnishes no criterion upon which to base a choice of climate, the indications for high altitude in uncomplicated and in not too far advanced cases being highly imperative, independent of this single manifestation; (2) That an exceedingly small proportion of recurrences may be expected in Colorado, although not necessarily re-

flecting accurately the degree of ultimate improvement secured; (3) That recurrences are more likely to result, and that quickly, in those cases with hemorrhage immediately preceding arrival, and hence the wisdom of a short delay following the hemorrhage before leaving home and unusual precautions as regard rest upon arrival; (4) That primary hemorrhages are comparatively rare in Colorado and usually take place incident to a rapid progressive destructive change in cases already with hopeless prognosis, or as a natural result of some external assignable cause, which under proper régime could be avoided; (5) That hemorrhage, while less likely to occur in Colorado than at sea-level, is, nevertheless, as a general rule, more severe and associated with greater shock; (6) That the avoidance of hemorrhage, particularly in the early months of Colorado life, demands a most rigid compliance with detailed instructions. [T. M. T.]

3.—H. Arrowsmith says that there are a few routine procedures in the **symptomatic treatment of tuberculosis** which do more harm than good: (1) The use of cod-liver oil. The author says this may sound heretical, but he is convinced of its truth. It acts as an alternative by changing decidedly the oxidation processes of the system. But, unfortunately, its alternative effects are in the wrong direction, decreasing the perfection of the proteid oxidation and depriving the unfortunate patients of the single chance of recovery they might otherwise have retained. The free ingestion of it rapidly decreases the urea in the urine and increases the incomplete or imperfect products of nitrogenous waste. The more perfectly it is emulsified, the more detrimental it becomes, because thus it is more palatable and less likely to produce digestive disturbance and to be therefore refused entrance to the system. The emulsion also favors the absorption of immoderate quantities, thus exhausting the oxygen supply and rendering the suboxidation of the proteid molecule, with all its ill effect, doubly certain. It disturbs the digestion and prevents the utilization of other and more valuable forms of foodstuffs; (2) The indiscriminate use of opium derivatives and cough syrups, which upset the patient's digestion and nutrition and thus work him incalculable harm. The author's personal experience with heroin has been uniformly disappointing; (3) The treatment of the septic fever by the coal-tar antipyretics. [T. M. T.]

4.—In an article on the **prevalence and treatment of tuberculosis among the poor**, H. L. Fancher quotes from Dr. S. A. Knopf the following: "Consumption is an eminently preventable and curable disease. It is curable in nearly all climates. All that is needed for the treatment of consumption is relatively good, pure air, good food and plenty of it, the best hygienic and sanitary conditions, and a willingness on the part of the patient to submit himself to the constant guidance of his physician. Consumption is not merely a medical, but also a social disease." Dr. Knopf also lays great stress on the establishing of sanatoria which will not only be healing institutions, but also schools of hygiene where patients will learn from actual experience how to take care of their expectoration and to protect others from infection and themselves from reinfection, and what to do and what not to do in order to get well and remain well. [T. M. T.]

5.—W. R. Stone does not advise the placing of tubercular patients in general medical wards, for the reason that it is very hard to make these patients understand the seriousness of their disease, and, therefore, they will not use the sputum cups provided for them, but most often expectorate upon the floors of the wards, upon the bed clothes, or into the registers set in the floor. As we know, the sputum quickly dried by the hot air is circulated through the air in the wards and is inhaled by all the other patients and attendants. [T. M. T.]

THE NEW YORK MEDICAL JOURNAL.

October 12, 1901. (Vol. LXXIV, No. 15).

1. The Lane Lectures on the Social Aspects of Dermatology. MALCOLM MORRIS.
2. The Tonsils. ROBERT LEVY.
3. A Case of Peliosis Rheumatica (Schönlein's Disease). FAIRFAX IRWIN.
4. The Growth of New Bone from Periosteum. J. HERMANN BRANTH.
5. Laryngology and Its Place in Medical Education. HENRY L. SWAIN.

6. On the So-Called Gluten and Diabetic Foods of Commerce. H. C. SHERMAN and H. M. RYER.

2.—It. Levy, in his article on the tonsils, states that the structures known as the tonsils consist of the entire ring of lymphatic tissue which runs from the tonsilla pharyngea to the region of the Eustachian orifice, from there to the posterior rim of the velum palati, around the posterior palatal fold to the faucial tonsil, over the base of the tongue to the opposite side, and by the same direction back to the pharyngeal tonsil. Diseases affecting these parts are found at all ages, but it is especially interesting to note that those of the pharyngeal and faucial tonsils are associated in childhood, those of the faucial and lingual tonsils in adult life. The tonsils are subject to acute and chronic inflammation, infectious, to disturbances in the character of their secretions, and to development of hypertrophic and hyperplastic changes. These pathological processes must be considered as due to both local and constitutional causes. The local causes are dependent upon certain variations from the normal in the structure of the tonsils themselves, while the constitutional causes may be due to such systemic vices as rheumatism, lymphatism, or systemic infection from absorption through the tonsillar tissue. [T. M. T.]

4.—J. H. Braith places the ordinary inflammatory diseases of the bone in three classes: (1) Death of bone in its entirety occurs in acute osteomyelitis, or is caused by severe shock, crushing, or by infection. It involves the whole bone, including diaphysis, epiphysis, and medullary substance; (2) Caries means death of particles of spongy or of articular parts. In caries it often happens that the nidus of inflammation becomes encapsulated and the liquid matter absorbed—as, for instance, may take place in caries of the spine, in which inflammatory matter, in encapsulation, is walled off, and the destructive process comes to a stop, which we term a cure; (3) Necrosis means death of a part, a mass of compact tissue. In necrosis there is no end to the lesion until the dead bone-substance is out of the system. Certain inflammatory processes, such as those of syphilis, attack the epiphysis. Necrosis of parts of bone may be due to a disturbance in the vascular system, to a thrombus or an embolus in the Haversian canals or in a system of canaliculi, or to a form of infection as a consequence to some blood crisis. [T. M. T.]

6.—H. C. Sherman describes some of the samples of the so-called gluten and diabetic foods of commerce as follows: (1) Diabetic biscuit, intended for use only in diabetes, said to contain little starch and no sugar and to be harmless and allowable in all cases and curative in their effects. The analysis shows this sample to have practically the composition of ordinary soda crackers, such as sell from seven to ten cents a pound; (2) Gluten wafers, made tender by the addition of sweet butter and alleged to be "very useful in diabetes." Except for the fact that it is somewhat higher in fat, this sample has essentially the composition of dried bread made from the cheaper grades of ordinary flour; (3) Gluten of wheat. The detailed statement on the package recommends it for invalids, but does not especially mention diabetes. The analysis corresponds almost exactly with the average composition of ordinary Graham flour or the lower grades of baking flours; (4) A small hard cracker purporting to be made from the gluten of wheat mixed with water only. The composition of this sample is much like that of the preceding and closely resembles that of ordinary crackers made "with water only." (5) Gluten zwieback, recommended as very useful in diabetes. This contains nearly the same amount of gluten and of carbohydrates as the entire wheat flour; (6) The package in which this was sold was labeled "gluten wafers" without further statement or description. In the amount of gluten they closely resemble the preceding; (7) So-called crude gluten. This is very similar in composition to the sample of the entire wheat flour; (8) Wheat gluten. It is alleged for this gluten that a large portion of the starch has been removed, and it is added that experience shows that it is better adapted to all but exceptional cases than pure gluten, besides being more palatable and less expensive. This sample contained 48 times as much carbohydrate as protein, a proportion quite similar to that shown by the entire wheat flour and one which might readily be obtained by simply grinding selected wheat. Very

little, if any, starch could have been removed in the preparation of this sample, certainly by no means a "large proportion;" (9) Extra gluten biscuit, and said to contain no sugar and but a very small amount of starch—not over 10 per cent. This sample contained at least five times as much starch as should have been present according to the description under which it was sold. There was nearly twice as much protein in proportion to carbohydrate as in ordinary breadstuffs, but it still contained 2.6 times as much carbohydrates as protein; (10) A perfect food for diabetes, dyspepsia, and obesity. This food contains as much starch and nearly as much carbohydrate as the whole wheat flour purchased at the same time and analyzed by the same methods. It is considerably richer in protein, but must certainly be regarded as very far from a satisfactory gluten food; (11) Gluten biscuit, also diabetic gluten biscuit. This sample, the best of those examined, contains twice as much carbohydrate as protein, whereas the British products examined by Fielden contained only about one-tenth as much carbohydrate as protein. [T. M. T.]

1. A Brief Résumé of the Life Work of Ambrose Paré, etc. CHARLES GREENE CUMSTON.
2. Cretinism. CHARLES S. MILLET.
3. Association of Anemia with Chronic Enlargement of the Spleen. ARTHUR H. WENTWORTH.

2.—In the eastern part of France there are as many as 32 cretins per thousand, and 111 cases of goltre per thousand. In the whole of France over 125,000 cretins and idiots are believed to exist. In Switzerland and in Austria the number is fully as great. Less than 100 cases of the sporadic disease are all that have been reported in North America. In the treatment of cretinism thyroid gland is best given in powder, since it dissolves rapidly upon the tongue, and none is lost, even if the patient is unruly. It is best to begin with $\frac{1}{2}$ a grain, 3 times a day, and gradually increase it. Whenever the temperature goes above 100°, or the child becomes very nervous and does not sleep, the remedy must be diminished or stopped for a while. Later, when the nutritive changes are fully re-established, a very moderate dose once or twice a week may be sufficient. Millet reported 2 cases of the disease. [J. M. S.]

8. Section of Ophthalmology. J. A. LIPPINCOTT.
9. The Late Implanting of Glass Ball in Orbit, and Epithelial Lip Grafts Transplanted to Orbit. ADELINE E. PORTMAN.

1.—Ernest LaPlace discusses some unusual features of appendicitis and their treatment and urges early operation in this condition. In every fatal case of appendicitis there was a time when operation could have saved the patient. This is true no matter what complications have arisen in the eventual course of the disease. More dependence should be put upon muscle rigidity than upon the location and character of pain. When appendicitis is confined absolutely to the appendix itself, medical measures may be employed, but if these should not at once prove suc-

cessful, operation should be performed. Whenever the disease has extended beyond the appendix and has produced adhesions or possibly an abscess, the case should be operated upon. LaPlace advocates strongly the constant and persistent flushing of the peritoneal cavity in cases of peritonitis. He has found the method of continuous irrigation introduced by himself two years ago, to be most satisfactory in a number of cases of extensive peritonitis. The use of salt solution in this way lessens very much the absorption of septic materials. Precaution should be taken to see that the flow of the fluid is free and continuous; otherwise hydrostatic pressure is produced within the abdominal cavity which interferes with the function of the diaphragm. [J. H. G.]

2.—F. Gregory Connell gives the history of **intestinal suturing**. He details a number of objections to those sutures which leave the knot exposed in the general peritoneal cavity. The ideal location of the knot is within the lumen of the bowel. A method of anastomosis in which no portion of the suture is exposed in the peritoneal cavity and in which the knot lies within the lumen of the bowel is described and excellently illustrated. This suture permits the penetration of all the coats of the intestinal wall. It is claimed for it that it prevents leaking, is unyielding, and prevents adhesions taking place at the site of anastomosis. [J. H. G.]

3.—Beck contributes an article on "**modern aspects of congenital osseous malformations**." The article is illustrated. Some of these reproductions represent X-ray photographs. The cases which are reported and illustrated are the following: Non-osseous supernumerary digit and synostosis of the third and fourth metacarpus; supernumerary phalanx of the left little toe; congenital fracture of the radius and ulna; congenital absence of the radius and ulna; congenital absence of metacarpal and phalanges of the second, third and fourth fingers; congenital scapular asymmetry; congenital absence of one metatarsus and corresponding phalanges; congenital shortening of the right femur; congenital hypertrophy of toes; congenital dislocation of both hips; congenital absence of nasal bones and insufficient development of nasal processes of supra-maxilla. [F. J. K.]

5.—Wilmarth writes on the **diagnosis of the "backward child"**. The author mentions that there is no sharp line separating the "so-called" backward from the normal child, or between the feeble-minded and markedly backward child. He reaches the following conclusions, which we quote in substance:—"Delay in the mental development may be temporary or permanent. In the former case we should speak of the child as merely backward, in the latter, as feeble minded. When this condition is due to a lack of proper training, or to temporary ill health, it may often be entirely overcome by proper treatment. There has been no definite standard established upon which to decide whether a child is backward or not and we have no other guidance than by comparison with supposed normal children of the same age. The qualities on whose absence or faulty development we form our judgment are acuteness of perception, power of attention, strength of memory, accuracy in reasoning and judgment and growth of normal sense. Certain physical conditions are of aid in diagnosis of a backward condition, especially when considered in connection with delayed mental growth. Prominent among these are deformities; defects in or absence of articulate speech, not due to mechanical faults or deafness; defects in co-ordination and awkward gait; defective physical growth and lack of acuteness in different sense organs. There are none of these absolute pathognomonic, with the possible exception of lack of speech due to cerebral defect."

[F. J. K.]

6.—Makuen believes that the diagnosis of backwardness in children is not different and that the character of speech is a factor which aids in the diagnosis and prognosis of this condition. He deduces the following conclusions:

"1. It is not always possible to determine at a glance the cause of backwardness in children. 2. Backwardness in children is not always due to a central lesion, but may be the result of arrested cerebral development due to some abnormality of structure in the peripheral organs of speech. 3. A very common cause of backwardness in children may be some abnormality of structure in the peripheral organs of speech. 4. So closely are the speech centres related to the ideational centers of the brain that any impairment of the one generally results in a corresponding impairment of the other. 5. The best method of arriving at even a proximately correct prognosis in cases of backward children is to apply the speech test, or, in other words, to ascertain by careful study an experiment to what extent the faculty of speech may be improved, and it will be found that in those who are susceptible to training in what may be called the refinements of speech are the one for whom we may promise the best results, and that possibilities for general development will be proportional to the capacity for speech development." [F. J. K.]

7.—Wahrer makes a plea for the backward child. He emphasizes his remarks by stating that he does not mean the defective child, but one whose body and mind are normal and who is not a descendant of degenerate parents. He believes that too frequently we draw a comparison between the so-called backward child and the so-called bright child as our model. He closes his remarks by stating that "I crave a greater sympathy for the backward child." [F. J. K.]

8.—See *Philadelphia Medical Journal*, June 15, 1901, p. 1138.

AMERICAN MEDICINE.

October 12, 1901.

1. Uric Acid Fallacies. FRANK BILLINGS.
2. A Case of Anthrax of the Face; Operation; Recovery; with Exhibition of Patient. W. B. PLATT and H. C. OHLE.
3. The Diagnosis of Primary Laryngeal Tuberculosis. P. S. DONNELLAN.
4. Fibrin of the Blood. ROBERT L. WATKINS.
5. Kidney-Stone, Diagnosis and Treatment. DONALD MACRAE.
6. A Fatal Case of Tetanus, Treated with Antitoxin. LOUIS C. AGER.

1.—Frank Billings discusses **uric acid fallacies**, in which many of the theories concerning uric acid are expounded. He states that some of the fallacies of uric acid are: 1. That uric acid is toxic. 2. That it is a causative factor in any disease except gout. 3. That "uricæmia," meaning uric acid blood, exists. 4. That the chemic reaction of the blood may be altered by the use of medicinal quantities of the alkalies or by the diet. 5. That uratic deposits may be dissolved out by the administration of alkalies. 6. That litmia is a uric acid solvent of unusual potency. 7. That uric acid is an abnormal constituent of the urine. 8. That an excess of uric acid in the urine at one time or a deficiency at another time indicates an abnormal condition in reference to uric acid. 9. That rheumatism is due to uric acid. [T. L. C.]

2.—Platt and Ohle describe a case of anthrax in which operation was followed by recovery. The patient was a male, 16 years of age. The disease started as a vesicle with a brownish eschar surrounded by a brawny induration and was situated upon the right side of the face and neck. The patient worked in a brush factory. Five days after the onset of the trouble the patient had a temperature of 102-103, mental condition was clear, the whole right side of the neck and face was greatly swollen, and the right eye was closed. The swelling was firm and pitted on pressure. Over the site of the angle of the jaw was a raised wreath of vesicles. In the centre of the ring was a black area $\frac{1}{4}$ inch in diameter, below the level of the

vesicles but on a level with the skin. The necrotic portion of skin was thoroughly excised with a Paquelin cautery knife. A dressing of bichloride solution was then applied. An examination of the tissues removed showed the anthrax bacillus. The comparative freedom from pain is called attention to by the authors and contrasted with the severe pain which accompanies carbuncle and other conditions of a like nature. The thorough removal by the cautery is thought to be the best treatment. [J. H. G.]

3.—P. S. Donnellan discusses the diagnosis of primary laryngeal tuberculosis. The patient will complain of dryness and uneasiness about the throat followed later by dysphagia. Impairment of the voice is soon observed varying from slight hoarseness to complete aphonia. The cough is strident or brassy in proportion as the voice-producing structures are affected. Hemorrhages may occur from erosion of the laryngeal capillaries. There is usually slight fever toward evening with slight subnormal temperature toward morning. The disease may be taken for any other of the varieties of chronic laryngitis. The bacteriological and histological examinations are of the highest importance in arriving at a diagnosis of primary laryngeal tuberculosis and the employment of tuberculin is of value. It must not be forgotten that the absence of tubercle bacilli from the sputum, or from scrapings taken from the larynx, is not to be taken as exclusive evidence of the absence of the disease. [T. M. T.]

5.—Donald Macrae reviews the subject of kidney-stone with special reference to its diagnosis and treatment. He refers to the frequent mistakes which have been made in diagnosis. Kelly's waxed ureteral bougie and Harris' segregator have done much to aid diagnosis. The X-ray has been so perfected as to be a most reliable diagnostic measure at the present day in the hands of a competent man. "I believe that the time has arrived when it becomes our duty to subject each and every case of an affection pointing to a pathologic nephro-ureteral condition to the X-ray." [J. H. G.]

6.—Louis C. Ager reports a fatal case of tetanus, treated with antitoxin. The first symptoms appeared five days after the injury, a laceration of the left thigh caused by striking an old piece of sewer pipe. Eighty c.c. of tetanus antitoxin were administered subcutaneously on the sixth or seventh day. In addition, the routine of chloral and bromide treatment was carried out. The patient died at the close of the seventh day after the accident, three days after the first symptoms of tetanus, although the tetanus seizures were at no time very severe. [T. L. C.]

VRATCH.

June 16, 1901. (Vol. XXII, No. 24.)

1. On the Bacteriology of Acute Articular Rheumatism. V. E. PREDTETSHENSKI.
2. A Case of Tubercular Leprosy. V. PH. DEMITSH.
3. Histological Changes in the Post-partum Uterus in Cases of Acute Streptococcic Pyemia Treated With and Without Antistreptococcic Serum.

I. I. KLITIN.

4. Operation in Mechanical Dysmenorrhea. S. A. ALEXANDROFF.

1.—Predtetshenski made a bacteriological study of 5 cases of acute articular rheumatism, employing special media and methods for the cultivation of Achalmé's bacillus and Wasserman's streptococcus, should the latter be present. In neither of the cases was Achalmé's bacillus found. In 3 the cultures remained sterile, while in 2, anaërobic cultures of the blood on the medium devised by Achalmé resulted in a growth. In one a micrococcus was found possessing the following characteristics: the organism occurs in chains of 2, 3 or 4, forming much longer chains in fluid media; it stains well by Gram's method; and is a facultative anaërobe, growing well on ordinary culture media. Bouillon is rendered uniformly turbid; on agar the colonies are delicate and transparent; milk is coagulated; gelatine not liquefied. Morphologically, then, this organism resembles closely Wasserman's

streptococcus. Inoculations into animals produced a disease presenting the clinical picture of acute articular rheumatism in man. 10-15 days after the inoculation painful tumefaction appeared in the joints of the legs, principally the large joints, accompanied by fever, loss of weight and finally terminating in death. Autopsy showed marked inflammatory changes in and about the joints, the latter containing a small amount of a turbid fluid. In one of the guinea pigs a well developed endocarditis was found. The organism was recovered from the blood and joints of the dead animals. It proved non-pathogenic to rabbits, the latter showing only a slight reaction. In the other case the organism found was also a micrococcus very similar morphologically to the preceding, except that it grew more vigorously and formed shorter chains. Animal inoculations gave the following results: In one guinea pig the inoculation was followed by an elevation of temperature and loss of weight. These symptoms soon subsided. In 2 weeks painful swelling of the knee joints appeared, the animal being unable to use its limbs. Sodium salicylate was administered, but the animal died. The autopsy revealed hemorrhages into the tissues surrounding the large joints, pericarditis and endocarditis of the aortic valves. Intravenous injection of 0.8 c.c. of a bouillon culture in a rabbit was followed on the third day by an affection of the joints, becoming progressively worse and resulting in death on the 11th day. Autopsy showed an effusion of a turbid fluid into the joints. Another rabbit died on the 14th day after the inoculation, showing on autopsy marked vegetative endocarditis, but no affection of the joints. The organism was recovered from the lesions. It is noteworthy that the patient from whom this organism was originally obtained had a relapse and the same organism was found the second time. The author does not undertake to decide whether the two organisms are varieties or one and the same, but grown under somewhat different conditions, nor does he claim that the organisms are identical with Wasserman's. He does, however, refuse to accord to Achalmé's bacillus the specificity claimed for it by Achalmé and the Russian bacteriologists, Savtshenko and Melkich. [A. R.]

2.—Demitsh reports two sporadic cases of leprosy. One in a woman of 58, the other in a man 49 years old, with a good family and personal history. The first case is of anesthetic, the second of the tubercular variety. In the latter the lepra bacillus was found in the ulcers and the blood. [A. R.]

3.—Will be abstracted when concluded.

4.—Alexandroff believes that congenital antelexion and the accompanying narrowing of the internal os are manifestations of degeneration. This is evident from the fact that these patients show other degenerative conditions of the genital organs, tubercular disease of the lungs or a predisposition to it, various neuralgias, hysteria and hyperæsthesias. On that account treatment is of little permanent value and should be directed mainly towards the improvement of nutrition. Contrary to the statements made in the text-books, the anterior wall of the internal os is very thin while the posterior is very thick. Sims's operation, in the author's opinion, does not accomplish a radical cure. He devised a modification which consists principally in the removal of a wedge-shaped piece from the thickened posterior wall of the internal os. [A. R.]

2.—Will be abstracted when concluded.

3.—Klitin determined by a series of experiments on animals, performed at the Institute of Experimental Medicine of St. Petersburg, the histological changes in the uterus in puerperal septicæmia, as compared with the normal uterus. He also studied the effect of serum treatment in modifying these changes. In a previous work on the subject just published in the *Archiv Biologicheskich Nauk*, 1898,

he pointed out that clinical observations show the beneficial effects of antistreptococcic serum in more than 65% of the cases of puerperal septicemia. According to Fehling's statistics, recovery takes place in 60%. The therapeutic action of the serum is in direct proportion to its strength, which should not be below 1 to 7000. The serum acts best in pure streptococcal infection, and its application is indicated principally in the acute forms of the disease. If such are the results obtained at the bedside, the experiments on animals prove more conclusively the value of the serum. The present experiments show (1) that the changes in the uterine horns following the introduction of a virulent streptococcus are the same whether the organism is introduced into the cavity or the blood current. These changes consist in the formation of numerous extensive areas of necrosis in the mucous as well as the muscular layer. The areas of necrosis are filled with streptococci. The blood vessels are considerably dilated, being filled with granular masses and streptococci. The endothelium is swollen and in places absent. The parenchyma of the uterine horns is marked by a rarefaction of the tissue elements quantitatively as well as in their distribution. The reactive infiltration of granulation elements and leukocytes is either but slightly apparent or altogether absent. Such changes take place in the early as well as later puerperal infection. In the latter case involution of the uterus is retarded. (2) When infection takes place through the inoculation of the vaginal mucosa or subcutaneous tissue, the degree and extent of the changes in the uterine horns are in proportion to the lapse of time since delivery. In the earlier infection, the changes are the same as described above, with the exception that they are not so widely disseminated and the endothelium of the blood vessels is not affected. In cases of late infection, the changes are characterized by the formation of islands of hyaline degeneration of the muscular fibres. The cellular elements are more abundant and more closely set; the streptococci are fewer in number. The blood vessels are dilated and contain many of the formative elements of the blood. (3) In cases in which the serum was used, involution takes place with greater regularity and more rapidly, owing to the greater vitality of the tissues. The infiltration of granulation elements and leukocytes is marked. The morbid changes are characterized only by an engorgement of the blood vessels which, however, is not general. The streptococci are fewer and, morphologically and microchemically, present involution forms, having lost their original virulence. These peculiarities in cases of serum-treatment are observed alike in the early and late infection. (4) The serum places the tissue elements in such a condition that the toxic effect of the streptococci is minimized. (5) This accounts for the recovery of the inoculated animals treated with antistreptococcic serum. [A. R.]

4.—Minin achieved remarkable results by the use of electric light in the treatment of superficial wounds, burns and a few cases of skin eruptions. The effect of electricity in these cases depends on the light and not the heat, inasmuch as the best results are obtained with the light at a considerable distance from the body. Blue light constricts the blood vessels and produces marked anesthesia, while white light has the opposite effect. The anesthesia caused by blue light is as marked as that produced by cocaine, and the author employed it successfully in minor surgery. Two cases are cited in which superficial wounds were sewed up under the influence of blue light of 50 candle power, without the patient experiencing the least pain. Contusions due to falls were promptly cured by blue light. In one case, a burn of the first degree yielded to two applications of the blue light from a lamp of 50 candle power, each sitting lasting 10 minutes. In another case of injury to the mouth, throat and esophagus caused by the accidental ingestion of ammonia, several applications of the blue light accomplished a complete cure. The light was directed to the mucous membrane of the mouth and in front of the neck and chest. A case of rheumatic purpura was cured by the application of white light from a 50 candle power lamp followed for a few minutes by blue light from a lamp of 25 candle power. In another case of simple purpura 5 applications of the electric light resulted in a cure, after other remedial agents failed. The treatment also exerted a beneficial effect on the general nutrition of the patient. [A. R.]

5.—Sirkin-Schklovski reports a case of hysterical paralysis and aphasia in a laborer, 18 years old. For 2 days

prior to the attack he was morose and expressed a desire to die. He recovered in a few days. [A. R.]

1. On the Causation and Serum Treatment of Malignant Growths. G. M. VLAEFF.
2. On the Differentiation Between Diphtheria and Pseudo-diphtheria Bacilli. I. A. SCHABAD.
3. Changes of the Body Temperature and Pulse Under the Influence of Various Baths of the Same Temperature, and the Influence of the Material of the Bath Tubs on the Cooling of the Contents.

I. I. MAKAVEEFF.

1.—Vlaeff, working at the Pasteur Institute, found that *biastomycetes* (*saccharomyces hominis*) play an important role in the causation of malignant growths. They are found in malignant tumors of man and animals, can be isolated and cultivated in pure culture and reproduce the disease (cancer, sarcoma, adenoma, etc.) in dogs, rats and rabbits. The toxins of these *biastomycetes*, when injected into animals cause fatty degeneration of the liver, kidneys and heart. By repeated injections of gradually increased doses immunity may be produced, and the serum of immunized animals is capable of curing cancer in the incipient stages, or prolonging the life of the patient when the growth is far advanced. The author employed the serum obtained from immunized geese and donkeys in the treatment of malignant growths in 60 cases and obtained results which seem to establish the curative value of the serum. He is of the opinion that syphilis, rheumatism, decayed teeth, chronic gastro-intestinal catarrh, traumatism, alcoholism, cirrhosis of the liver, malnutrition and antihygienic conditions are predisposing factors in the causation of malignant growths. [A. R.]

2.—Schabad draws the following conclusions from a series of carefully conducted observations on the true and pseudo-diphtheria bacilli: (1) True and pseudo-diphtheria bacilli represent two distinct species. (2) They differ in the growth on nutrient media (principally agar and asetic fluid), in their morphology, reaction of the bouillon culture, staining by Neisser's method and pathogenicity. (3) The most constant differential characteristics are the reaction of the bouillon culture and Neisser's stain. (4) It is necessary to distinguish the pseudo-diphtheria from the non-virulent diphtheria bacilli which, except their loss of virulence, are identical with the true bacilli. (5) The confusion of the non-virulent with the pseudo-diphtheria bacilli is largely accountable for the observations on the production of acid by the latter and their staining with Neisser's stain. (6) The differentiation of the non-virulent diphtheria bacilli is possible in all cases by other characteristics. (7) Spronck's method gives unsatisfactory results with the non-virulent bacilli. An important point brought out by the author is that the acidity of the bouillon should be invariably determined by titration with phenolphthalein as an indicator. Litmus may show an alkalinity when an acidity of several degrees is actually present. It is to the use of litmus as an indicator that he ascribes the failure of some observers to find an increased acidity in all cases of true diphtheria cultures. Behring's latest assertion that one of his diphtheria cultures produces no acidity is explained in the same way. [A. R.]

1. The Influence of X-Rays on the Diagnosis and Treatment of Fractures. H. H. CLUTTON.
2. On the Use of Massage, Early Movement, and Posture in the Treatment of Recent Fractures.

WILLIAM H. BENNETT.

3. The Operative Treatment of Simple Fractures.

C. H. GOLDING-BIRD.

1. Recent Advances in the Diagnosis and Treatment of Fractures of the Upper Extremity. J. E. PLATT.

2.—William H. Bennett discusses the use of massage, early movements, and posture in the treatment of recent fractures. The method has never been advocated to the entire exclusion of the use of splints or of operation in the treatment of recent fractures, but the author believes that it should be used discreetly as an adjunct to the ordinary methods, and modified as circumstances may demand. The method entirely obviates the stiffness, pain and other

disadvantages which so constantly follow the treatment of fractures upon classical lines. Discussing massage, the author states that the amount of movement, if any, which occurs in the proper application of this method is not sufficient to interfere in any way with union, and need not, therefore, stand in the way of the application of common sense principles. The ease with which a difficult fracture can be manipulated after it has been subjected to gentle, smooth rubbing is often a revelation to those who have had no experience in the matter. The object of early passive movement in recent fractures is the very simple one of preventing adhesions, as opposed to the results of the older methods of absolute fixation of the limb. In any cases of fracture, after the fragments have been placed in accurate position, passive movements should be begun at once. The earliest movements can be effected without the removal of the splints, but in every case, as soon as the state of the fracture permits (from the third or fourth day onward) the splints should be loosened for gentle massage, by which the passive movement is not only rendered more easy, but also more effectual. The main points in making passive movements are the following: (1) Steady fixation of the fracture itself should be insured, either by the grasp of the hand or by appropriate splints or apparatus. (2) All movements must be gently but deliberately made, the hand must be firm and unhesitating, although gentle. In this way a sense of certainty and confidence is imparted which generally removes any inclination to resistance on the part of the muscles. It may be wise to practice movements first on the sound limb. In order to give the muscles some idea of what is expected of them. For the completely efficient employment of massage and early movements, the proper position of the affected limb is a matter of much moment. The danger of thrombosis and embolism, feared by some surgeons, does not exist more than in fractures treated by prolonged splinting. The method is not suited to those who lack discretion or who are defective in dexterity. The principal disabilities attaching to the union of fractures in faulty positions, unless the displacement be gross or of the rotary kind, are avoidable by the use of massage and early movements, by which adhesion around the fracture is prevented. [T. L. C.]

3.—C. H. Golding-Bird treats of the operative treatment of simple fractures, both simple and compound. Skiagraphy, notwithstanding the aid which it affords in diagnosis, must not be the sole test of the surgeon's work, nor indolence the standard up to which operative procedures should be carried. The value of massage as an adjunct of treatment is emphasized. He does not recommend open operation for Pott's fracture in the greater number of cases, but where restoration of position, after treatment of splints has not succeeded, and open operation is both safe and the ideal treatment. Some surgeons use the osteo-elast. The technique of the various operations used are discussed. As to fracture of the patella, it has been for many years his custom to operate by transverse methods by wiring and it has been universally successful. The treatment of separation of epiphyses and vicious and distorted union; non-union, and the operation of bone grafting are described; as is also the treatment of compound, or open fractures. [T. L. C.]

4.—J. E. Platt discusses the recent advances in the diagnosis and treatment of fractures of the upper extremity. No marked advance has been made during recent years in the diagnosis and treatment of fractures of the clavicle. The frequency of the incomplete fracture of the clavicle has been pointed out by several authors. If the displacement is considerable, an attempt should be made to remedy it by direct pressure, but care must be taken to avoid making the incomplete fracture complete. The arm should be kept at rest for from 10 to 14 days. The callus-tumor is usually completely absorbed in the course of time, but the process of absorption may take several months. The treatment of fractures by early massage without immobilization has been strongly recommended by Lucas-Championnière. Primary wiring has also been recommended. The author discusses fractures of the scapula and the humerus. In speaking of the treatment of fractures of the humerus, he has discarded passive movement after considerable experience with this method. Fractures of the radius and ulna are also mentioned, as well as many unusual fractures of the upper extremity. [T. L. C.]

6. A Series of Twelve Articles on Medical Men Prominent in the Civil and Military Affairs of Revolutionary Times—IV. FRANCIS R. PACKARD.

1.—See the Philadelphia Medical Journal, Issue of June 15th, 1901.

2.—Alfred Stengel reports a series of 17 cases of right-sided cardiac hydrothorax. Of the 17 cases, 5 were instances of effusion on the right side only. The evidence of effusion in one of the 5 cases being somewhat questionable. Three were cases of left-sided effusion, in two of which the right pleura was found entirely obliterated at autopsy, and in the third there was a suspicion of an aneurysm in the left chest; 9 cases had bilateral effusion at some stage; 2 of these were first right-sided, then bilateral with less extensive effusion on the left side; in the other 7 the effusion was bilateral from the beginning, but the right side was particularly affected. In discussing the causation of this condition, Stengel refers to two autopsies in which there was purely dilatation of the right ventricle, auricle and vena cava, and marked backward pressure upon the root of the right lung and azygos vein was discovered. From these facts it is evident that pressure is the predominating cause of the effusion in the right side. Stengel says that he has reached this opinion independently, but it has been expressed by others. Anatomical relations of the azygos vein to the inferior vena cava and right auricle below and to the bronchus and vessels at the root of the right lung above. Even a moderate dilatation of the auricle and cava must of necessity exercise a considerable pressure on the azygos vein and thus reduce its lumen. On the left side conditions are very different. The higher position of the left auricle prevents pressure of the lower azygos vein, which receives the intercostal veins up to the 6th or 7th interspaces and then empties into the major azygos, after crossing the vertebral column. The upper left azygos vein drains but one or two intercostal spaces, and is so placed as to be little likely to be compressed. The left superior intercostal vein is quite out of reach of compression, and it flows upward, so that even a compression of its lower part could have but little effect. These facts show the readiness with which dropsical effusions of the right chest may be occasioned by dilatation of the right auricle with direct and indirect pressure. The latter by displacement of the root of the right lung of the major azygos vein. Secondary and less extensive effusion in the left chest is explained by the fact that the lower and upper azygos veins of the left side discharge into the major azygos. Obstruction of this vessel would therefore occasion immediate and complete venous stasis in the right chest and secondary stasis in the lower portion of the left chest, and bear out completely the clinical observations. [T. L. C.]

3.—Spiller, Robertson and W. S. Wadsworth discuss the subject of cerebellar lesions without cerebellar symptoms. They report 3 cases, one in which there was a cerebellar tumor; the second in which there was the tumor of the corpora quadrigemina, and the third case was marked congestion of the brain and slight edema. The left cerebellar was quite firm and remarkably reduced in size. The left vertebral artery was smaller than the right, not gaping and having a scar as of an old local arteritis. In none of these cases were symptoms present. [T. L. C.]

4.—Riesman reports a case of complete unilateral oculomotor palsy. The patient was a man of 39 years, who had a specific history. He was placed under appropriate treatment and was in perfect health for six years, then began to suffer from dizziness and a sense of oppression in the head, and some disturbance of vision in the left eye. There was complete ptosis of the left upper eyelid with marked elevation of the left eyebrow by reason of a tonic

contraction of the corresponding frontalis muscle. The left pupil was much dilated, while the right was of medium width. There was no reaction to light or accommodation in the left eye, while the right eye reacted well. At rest the left eyeball deviated slightly outward and could not be carried inward beyond the median line. When the patient attempted to look to the right, an attempt to detect the presence of the retracted levator palpebrae failed. Riesman concludes that the region is situated in the trunk of the nerve, and believes that it is of a nature either of circumscribed gumma or of a gummatous neuritis. [T. L. C.]

5.—Dr. Edward W. Reichert gives an admirable description of some forms of apparatus used in the course of practical instructions in physiology in the University of Pennsylvania. A model laboratory is described, as well as a system of recording apparatus and the system of exciting apparatus. All of the instruments, numbering over 200,000 pieces, were made in the laboratories of the University. A model kymograph is described, as well as a frog table, muscle chamber, moist chamber and the signal and vibrating reed. The system of exciting apparatus which is described includes the inductorium, the hand electrodes, the rheocord and the rheonome. [T. L. C.]

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

Fiftieth Annual Meeting Held at Philadelphia, September 24-25, 26th, 1901.

(Continued from Page 599).

The perforation was sutured, the abdomen flushed with sterile salt solution, closed and drained, the whole of the operation occupying but sixteen minutes. The perforation was large enough to admit the tip of the finger, and from it there was discharged food and milk. The patient was in a precarious condition throughout the operation during which camphor was administered hypodermically. Notwithstanding, the patient recovered. The author concludes that this case seems to teach that a case of perforation even with general peritonitis should be operated upon, and quickly, and that general anesthesia can be borne even by a patient in so critical a condition. When the element of fright is in abeyance, local anesthesia can be employed, but not in children. The literature on the subject was quoted and the paper discussed by Dr. Herman B. Allen and Dr. Ella B. Everett, of Philadelphia, who saw the case before surgical measures were needed.

A Case of Ascites Due to Hepatic Cirrhosis, Treated by Transplanting the Omentum between the Peritoneum and Abdominal Wall; Result with Autopsy Eight Months Later and Exhibition of the Abdominal Viscera, Showing Specimen and Horseshoe Kidney by Dr. W. J. Roe, of Philadelphia.

Address in Obstetrics by Dr. David Funk, of Harrisburg. The address was opened with the statement, that never before has the parturient mother been so little surrounded by danger as at the present time. The increase in manipulative skill, the improved mechanical appliances, the immediate repair of the soft parts, the eradication of puerperal sepsis, the clearer conception of the relations between mother and child, and the appreciation of the difference between midwifery and medicine, all surround the lying-in woman with a protecting barrier. The paper dealt with the more serious obstacles that are encountered. The author quoted the high mortality both of mother and child in placenta, due unfortunately to the absence of prophylaxis. The condition is very rare and not much real progress has been made beyond what has been known for many years, namely the early emptying of the uterine con-

tents, which should be followed immediately after the diagnosis has been made. Manual dilatation and version have not done as much as has been promised of them. Symphysiotomy is being supplanted by Cesarean section, the latter entailing a briefer convalescence, a reduction of mortality to a minimum, that of the fetus being practically all. There has been nothing new during the year regarding the prophylaxis of puerperal sepsis, and stress was laid upon the rigid observation of surgical cleanliness. Serumtherapy in the treatment of puerperal sepsis is still in its experimental stage and in the presence of mixed infection is valueless. Ectopic gestation occurs more frequently than has formerly been supposed, and the general practitioner must be watchful for it. It has a fairly uniform symptomatology and the patients generally fail to seek medical advice until the condition has become severe. Especially therefore should the general practitioner be careful in his diagnosis, notably when an ectopic pregnancy and an intrauterine pregnancy co-exists. There is no excuse in confounding colic, dysmenorrhea and ovarian congestion with ectopic gestation. The most likely conditions to be confounded with ectopic gestation, are pyosalpinx and ovarian abscess. The subject of eclampsia was next to be taken up and the author stated that beyond the recognition of toxemia in these cases there was much confusion. The various theories were then discussed. Prophylaxis consists in careful attention to diet, the emunctories and hygiene. The eclamptic state requires the administration of large quantities of liquid. Morphine and chloroform have been highly recommended as well as condemned. In the case of these two drugs, one has been condemned by the advocates of the other, the objection in the case of morphine being that it arrests most of the secretions. Enteroclysis, intravenous injections, and hypodermoclysis and hot baths are to be used. Bromide of sodium, chloral hydrate as well as chloroform and morphine still are valuable adjuncts. Serumtherapy in the treatment of eclampsia is still to be regarded as a problem of the future.

The Ultimate Results of Operations for Cancer of the Uterus by Dr. Charles P. Noble, of Philadelphia. Dr. Noble referred to the marvelous progress that had been made in gynecological surgery which however unfortunately did not embrace cancer of the uterus. He reported the statistics of cures in the various American and foreign clinics and also discussed the removal of the uterus, pelvic glands and parametria. He reported the results of thirty-two cases, twenty-two of the cervix and nine of the corpus.

A Report of a Case of Double Extra-uterine Pregnancy by Dr. F. P. Hall, of Philadelphia, who reported a case of double extrauterine pregnancy, and briefly referred to the frequency of this complication and the necessity of the family doctor to make an opportune diagnosis. Many cases are not diagnosed because the product of conception mummifies or becomes encysted, producing much misery and pain. In a case of pregnancy with sudden abdominal pain, and symptoms of shock and syncope we should expect extrauterine pregnancy with rupture.

Dr. J. V. Shoemaker presented a case of pityriasis versicolor, and gave a comprehensive description of the symptoms and physical science of this parasitic skin disease. He describes the differential diagnosis between chloasma, pityriasis versicolor and vitiligo. He called attention to the etiological factor, the microsporon furfur and the detection of the spores and mycelia. He stated that it is one of the most difficult skin diseases to cure as it penetrates the hair follicles, thus proving refractive to superficial medications. Bichloride of mercury solution will only affect it on the surface. Copper is the best remedy, preferably in the form of the oleate on account of its penetrative ability. Mercury in the form of the oleate is also valuable. It is imperative to keep water from the skin as the parasite thrives on water.

(To be continued.)

Special Article.

THE CASE OF PRESIDENT MCKINLEY.

The following report has received the approval of, and is issued by, the undersigned, the medical staff attending the late President, William McKinley.

P. M. RIXEY.
MATTHEW D. MANN.
HERMAN MYNTER.
ROSWELL PARK.
EUGENE WASDIN.
CHARLES McBURNEY.
CHARLES G. STOCKTON.

October 12, 1901.

SURGICAL HISTORY.

President William McKinley was shot, by Leon F. Czolgosz, in the Temple of Music, at the Pan-American Exposition, Buffalo, N. Y., at about 7 minutes past 4 on the afternoon of Friday, September 6, 1901. Two shots were fired. One bullet struck near the upper part of the sternum, and the other in the left hypochondriac region. The President was immediately conveyed to the Emergency Hospital on the Exposition grounds by the motor ambulance, where he arrived at 4.18. Dr. G. McK. Hall and Mr. Edward C. Mann, medical student, of the house staff, were in charge of the ambulance, Medical Student T. F. Ellis being the driver.

On arriving at the hospital, President McKinley was at once placed upon the table in the operating room and undressed. During the removal of his clothing a bullet fell out and was picked up by Mr. Ellis. Dr. Hall placed a temporary antiseptic dressing over the wounds, and Mr. Mann ordered a nurse to administer 0.01 gm. of morphin and 0.002 gm. of strychnin hypodermically.

Dr. Herman Mynter, who had been telephoned from police headquarters to report immediately at the Exposition Hospital, was the first surgeon to arrive, at 4.45 o'clock. At that time Drs. P. W. Van Peyma and Joseph Fowler, of Buffalo, and Dr. Edward Wallace Lee, of St. Louis, were present. Dr. Mynter brought with him Dr. Eugene Wasdin, of the United States Marine-Hospital Service.

Dr. Mynter inspected the President's wounds, and immediately saw their serious nature. He told the President that it would be necessary to operate, and at once set about making preparations, aided by the house staff and nurses and Dr. Nelson W. Wilson, Sanitary Officer of the Exposition, who at that time assumed charge of the hospital in the absence of Dr. Roswell Park, the Medical Director of the Exposition. The President's pulse on the arrival of Dr. Mynter was 84; he had no particular pain in the abdomen, and no apparent loss of liver dulness. He was evidently slightly under the influence of the morphin.

Dr. Matthew D. Mann arrived at the hospital at 5.10 P. M., having been telephoned for by Mr. John C. Milburn. He was followed, five minutes, later, by Dr. John C. Parmenter.

An examination was at once made, followed by a short consultation between Drs. Mann, Mynter and

Wasdin, which resulted in the decision to operate at once. The necessity for the operation was explained to President McKinley, and he gave his full consent. Immediate operation was decided upon because of the danger of possible continued internal hemorrhage and of the escape of gastric or intestinal contents into the peritoneal cavity, and because the President's pulse was getting weaker. Moreover, the daylight was rapidly failing. Dr. Roswell Park, who, by virtue of his office, had he been present would have performed the operation, was at Niagara Falls, and although a special train had been sent for him, it was uncertain when he would arrive.

Dr. Mann was selected to do the operation, with Dr. Mynter as his associate, by the common consent of the physicians present and at the request of Mr. Milburn, president of the Pan-American Exposition, who stated that he had been requested by President McKinley to select his medical attendants. Dr. Mann selected Drs. Lee and Parmenter as assistants.

At 5.20 Dr. Mann directed the administration of ether to President McKinley, and requested Dr. Wasdin to administer it. Ether was chosen as being, on the whole, the safer anesthetic. While the anesthetic was being given, the surgeons who were to take part in the operation prepared their hands and arms by thoroughly scrubbing with soap and water and immersing them in a solution of bichlorid of mercury.

The operation began at 5.20. Dr. Mann stood upon the right-hand side of the patient, with Dr. Parmenter on his right-hand side. Dr. Mynter stood upon the left-hand side of the patient, and on his right was Dr. Lee. To Drs. Parmenter and Lee were assigned the duties of sponging and the care of the instruments. Dr. P. M. Rixey, U. S. N., President McKinley's family physician, having been detailed by the President to accompany Mrs. McKinley to the Milburn home, did not arrive until 5.30, when he gave very efficient service by guiding the rays of the sun to the seat of the operation by aid of a hand-mirror, and later by arranging an electric light. Dr. Roswell Park arrived just as the operation on the stomach was completed, and gave his aid as consultant. Mr. E. C. Mann had charge of the needles, sutures and ligatures. Mr. Simpson, medical student, was at the instrument tray.

The nurses, under the charge of Miss A. C. Walters, superintendent of the hospital, were Miss M. E. Morris and Miss A. D. Barnes, with hands sterilized; Miss Rose Baron, Miss M. A. Shannon and Miss L. C. Dorchester, assistants, and Miss Katharine Simmons attending the anesthetizer.

Besides those immediately engaged in the operation, there were present Drs. P. W. Van Peyma, Joseph Fowler, D. W. Harrington and Charles G. Stockton, of Buffalo, and Dr. W. D. Storer, of Chicago.

THE OPERATION.

President McKinley took the ether well, and was entirely under its influence in nine minutes after the beginning of anesthetization. The abdomen was carefully shaved and scrubbed with green soap, and then washed with alcohol and ether and the bichlorid solution.

Inspection showed two wounds made by the bullets. The upper one was between the second and third ribs, a little to the right of the sternum. The use of a probe showed that the skin had not been penetrated, but that the bullet had probably struck a button or some object in the clothing which had deflected it. The lower wound made by the other bullet—a 32 calibre—was on a line drawn from the nipple to the umbilicus. It was about half-way between these points, and about 5 cm. to the left of the median line. A probe showed that this wound extended deeply into the abdominal walls, and that the direction was somewhat downward and outward.

An incision was made from the edge of the ribs downward, passing through the bullet wound and nearly parallel with the long axis of the body. A deep layer of fat was opened, and followed by incision of the fascia and muscles to the peritoneum. After cutting through the skin, a piece of cloth, undoubtedly a bit of the President's clothing, was removed from the track of the bullet, a short distance below the skin.

On opening the peritoneum, the finger was introduced and the anterior wall of the stomach palpated. An opening was discovered which would not quite admit the index finger. This opening was located near the greater curvature of the stomach, and about 2 cm. from the attachment of the omentum; its edges were clean-cut and did not appear to be much injured.

The stomach was drawn up into the operation wound, and the perforation very slightly enlarged. The finger was then introduced and the contents of the stomach palpated. This was done to see if the stomach contained food, and also with the hope that possibly the bullet might be in the stomach. The stomach was found to be half full of liquid food, but no evidence of the ball was discovered. In pulling up the stomach, a small amount of liquid contents escaped, together with a good deal of gas. The tissues around the wound were carefully irrigated with hot salt solution and dried with gauze pads. The perforation in the anterior stomach wall was then closed with a double row of silk suture (Czerny-Lembert). The sutures were not interrupted with each stitch, but four stitches were introduced before the ends were tied. The loop was then cut off and the suture continued. About eight stitches were used in each row. The silk used was fine black silk, the needle being a straight, round sewing needle.

In order to examine the posterior wall of the stomach, it was necessary to enlarge the incision, which now reached about 15 cm. in length. The omentum and transverse colon were pulled well out of the abdomen. The omentum was enormously thickened with fat and very rigid. In order to reach the back wall of the stomach, it was necessary to divide about four inches of the gastrocolic omentum, the cut ends being tied with strong black silk in two masses on each side. In this way the stomach could be drawn up in the operation wound, and the bullet wound in its posterior wall reached. This opening was somewhat larger than that in the anterior wall of the stomach, and had frayed and blood-infiltrated edges. Its exact location was im-

possible to determine, but it appeared to be near the larger curvature.

This opening was closed in the same way as the anterior wound, but with great difficulty, as the opening was down at the bottom of a deep pocket. A short curved surgical needle was necessary here. Little or no gastric contents appeared around this opening, but, after it had been closed, the parts were carefully irrigated with hot salt solution.

The operation on the stomach being now finished, Dr. Mann introduced his arm so as to palpate carefully all the deep structures behind the stomach. No trace of the bullet or of the further track of the bullet could be found. As the introduction of the hand in this way seemed to have a bad influence on the President's pulse, prolonged search for further injury done by the bullet or for the bullet itself was desisted from. The folds of the intestine which had been below the stomach were inspected for injury, but none was found. The entire gut was not removed from the abdomen for inspection, as the location of the wound seemed to exclude its injury. To have made a satisfactory search for wounds in the President's back, it would have been necessary to have entirely eviscerated him. As he was already suffering from shock, this was not considered justifiable, and might have caused his death on the operating table.

Before closing the abdominal wound, Dr. Mann asked each of the surgeons present, whether he was entirely satisfied that everything had been done which should be done, and whether he had any further suggestion to make. Each replied that he was satisfied. The question of drainage was also discussed. Dr. Mynter was in favor of a Mikulicz drain being placed down behind the stomach-wall. Dr. Mann, with the concurrence of the other surgeons, decided against this, as being unnecessary.

As the last step in the operation, the tissues around the bullet track in the abdominal wall were trimmed, in order to remove any tissue which might be infected. The abdominal wound was then closed with seven through-and-through silkwormgut sutures, drawn only moderately tight, the superior layer of the fascia of the rectus muscle being joined with buried catgut. The edges of the skin were brought together by fine catgut sutures. Where the bullet had entered there was slight gaping of the tissues, but it was not thought advisable to close this tightly, as it might allow of some drainage. The wound was then washed with hydrogen dioxide and covered with aristol powder and dressed with sterilized gauze and cotton, which were held in place with adhesive straps. Over all was put an abdominal bandage.

The President bore the operation very well. The time from the beginning of the administration of the anesthetic until its discontinuance was exactly an hour and thirty-one minutes; the operation was completed at 6.50 P. M., having lasted, from the time of the first incision, an hour and twenty-one minutes. At the beginning of the operation President McKinley's pulse was 84. At 5.38, 0.002 gm. of strychnin was administered hypodermically. At 5.55 the respiration was 32 and the pulse 84—both good in character. At 6.09 the pulse was 88. At 6.20 it was 102, fair in character; respiration 39. At

6.22, 1.50 gm. of brandy was administered hypodermically. At 6.48 the pulse was 124, the tension good but quick; respiration 36. At 7.01, after the bandage was applied, the pulse was 122 and the respiration 32. At 7.17, 0.004 gm. of morphin was administered hypodermically.

At 7.32 the patient was removed from the hospital in the ambulance. Dr. Rixey asked Drs. Park and Wasdin to go in the ambulance, as his duty called him to go at once to inform Mrs. McKinley of her husband's condition and to prepare a room for his reception. Drs. Mann and Mynter, with friends of the President, followed in carriages immediately after. President McKinley had not then recovered from the anesthetic. He bore the journey to Mr. Milburn's house exceedingly well, but it was found necessary to give him a small hypodermic injection of morphin during the transit, as he was becoming very restless. On arrival at the house of Mr. Milburn, 1168 Delaware Avenue, he was removed from the ambulance on the stretcher, and carried to a room in the northwest corner of the house, where a hospital bed had been prepared for him.

REMARKS ON THE OPERATION.

By DR. MATHEW D. MANN, M. D.,

The difficulties of the operation were very great, owing partly to the want of retractors and to the failing light. The setting sun shone directly into the room, but not into the wound. The windows were low and covered with awnings. After Dr. Rixey aided us with a hand mirror, the light was better. Toward the end of the time a movable electric light with reflector was put in use. The greatest difficulty was the great size of President McKinley's abdomen and the amount of fat present. This necessitated working at the bottom of a deep hole, especially when suturing the posterior wall of the stomach.

The operation was rendered possible and greatly facilitated by a good operating table and the other appliances of a hospital, and by the presence of many trained nurses and assistants. Still, the hospital was only equipped for minor emergency work, and had but a moderate supply of instruments. Unfortunately, when called I was not told what I was wanted for, and went to the Exposition grounds entirely unprepared. Dr. Mynter had his large pocket case, the contents of which were of great use.

As has already been noted, further search for the bullet was rendered inadvisable by the President's condition. The autopsy shows that it could not have been found, and that the injuries inflicted by the bullet after it passed through the stomach, were of such a nature as to render impossible and unnecessary any further surgical procedure. A bullet after it ceases to move does little harm. We were often asked why, after the operation, we did not use the X-ray to find the bullet. There were several reasons for this. In the first place, there were, at no time any signs that the bullet was doing harm. To have used the X-ray simply to have satisfied our curiosity would not have been warrantable, as it would have greatly disturbed and annoyed the patient, and would have subjected him also to

a certain risk. Had there been any signs of abscess formation, then the rays could and would have been used.

My reason for not draining was that there was nothing to drain. There had been no bleeding nor oozing; there was nothing to make any discharge or secretion; the parts were presumably free from infection, and were carefully washed with salt solution. As there was no peritonitis and the abdomen was found post mortem to be sterile, we may safely conclude that no drainage could have been provided which would have accomplished anything. My experience teaches me never to drain unless there is a very decided indication for it, as a drain may do harm as well as good.

In conclusion, I wish to thank all the gentlemen who so kindly and skilfully assisted me. They were all surgeons of large experience in abdominal surgery, and their aid and advice were most valuable. Especially I wish to acknowledge my great obligation to my associate, Dr. Mynter. Not only was he an assistant, but he was much more, and helped me greatly by his skill, and as a consultant, with his good judgment and extensive knowledge of abdominal work. Although called first, he waived his claim, and generously placed the case in my hands, willingly assuming his share of the responsibility.

The anesthetic was most carefully administered by Dr. Wasdin, and the knowledge that he had charge of this very important duty relieved me of any anxiety on that score.

In the eventful week that followed the operation, Dr. Park and Dr. McBurney were towers of strength in helping to decide the many difficult questions which came up.

Dr. Rixey was in constant charge of the sick room, aided later by Dr. Wasdin, who was detailed for this special duty. Both were unremitting in their care, and faithful to the end.

Dr. Stockton helped us in the last three days with the highest skill and best judgment.

Never, I am sure, under like circumstances, was there a more harmonious or better-agreed band of consultants. That our best endeavors failed was, I believe, no fault of ours; but it must be an everlasting and keen regret to each one of us, that we were not allowed the privilege of saving so noble a man, so attractive a patient, and so useful a life.

THE AFTER TREATMENT.

When put to bed the President was in fair condition: Pulse 127; temperature 100.6°; respiration 30. The nurses on duty were Miss K. R. Simmons and Miss A. D. Barnes, from the Emergency Hospital. Soon after his arrival, at 8.25, he was given morphin, 0.016 gm., hypodermically. There was slight nausea. The pulse soon improved. During the evening the patient slept at intervals, vomiting occasionally, but rallied satisfactorily. A slight discoloration of the dressings was noted at 10.45. There was occasional and slight pain. Ninety cc. of urine were voided, and an enema of salt solution given and retained.

SECOND DAY, SATURDAY, SEPTEMBER 7.

After midnight the patient slept a good deal; he was free from pain and quite comfortable.

At 6 a. m., the temperature was 102°; pulse 110; respiration 24.

Gas in large quantities was expelled from the bowels. A saline enema was given as before. Miss Simmons and Miss Barnes were replaced by Miss Maud Mohan and Miss Jane Connolly. Miss E. Hunt, of San Francisco, Cal., Mrs. McKinley's nurse, also rendered assistance, and Miss Grace Mackenzie, of Baltimore, Md., arrived September 9, and was detailed for regular duty. P. A. Eliot, J. Hodgins and Ernest Vollmeyer, of the U. S. A. Hospital Corps, were detailed as orderlies.

During the forenoon, 0.01 gm. of morphin was administered hypodermically.

At 1.15 p. m., a saline enema of 500 cc. was given. As the pulse was rising, 0.06 gm. of fluid extract of digitalis was injected hypodermically.

The President rested quietly until 6.30 p. m., when he complained of intense pain in the pit of the stomach, and was given 0.008 gm. morphin sulfate hypodermically. He was very restless, but after being sponged rested again.

At 6.30 p. m., the pulse was 130; temperature 102.5°; respiration 29.

During the day the digitalis, morphin, and saline enemas were kept up at regular intervals; 4 gm. of somatose was added to the water at 10.30 p. m. At 11.15 p. m. the President passed from the bowels 240 cc. of a greenish colored fluid and some particles of fecal matter.

The total amount of urine for 24 hours was 270 cc.

FIRST URINALYSIS, BY DR. H. G. MATZINGER.

Quantity..... 30 cc.
Color..... dark amber
Reaction..... strongly acid
Urea..... 0.928 gm. per 1 cc. of urine
Albumin..... a trace
Phosphates and Chlorids..... normal
Sugar..... none.
Indican..... very small amount.

Microscopic Examination.—The sediment obtained by centrifuge shows a large amount of large and small epithelial cells with some leukocytes and occasional red cells. There is a comparatively large number of hyaline casts, principally small, with some finely granular ones; also an occasional fibrinous one. The amount of sediment is large for the quantity of urine submitted. There were no crystals in the sediment.

THIRD DAY, SUNDAY, SEPTEMBER 8.

During the early morning the President slept a good deal, but was restless, and at times confused and a little chilly. On the whole, he passed a fairly good night.

He expelled a little gas and brown fluid from the rectum. The digitalis was continued, and at 7.45 a. m., 0.002 gm. of strychnin were given hypodermically. At 8.26 a. m. he was clear and bright, with the pulse strong and of good character.

The wound was dressed at 8.30, and found in a very satisfactory condition. There was no indication of peritonitis. Pulse, 132; temperature, 102.8°; respiration, 24.

The dressing on the wound was changed, because there was some exudation. The bullet track was syringed out with hydrogen dioxide. There was very little foaming, and there were no signs of pus.

At 10.40 a. m., following an enema of epsom salts, glycerin and water, he had a small stool with gas, and another at noon. He was less restless and slept a good deal.

At noon Dr. Charles McBurney joined the medical

staff in consultation having been summoned by Dr. Rixey.

Bulletin 14, 12 m.—The improvement in the President's condition has continued since the last bulletin. Pulse, 128; temperature, 101°; respiration, 27.

During the day he continued to improve; he slept four or five hours and his condition was satisfactory.

At 4.45 p. m., he was given a teaspoonful of water by the mouth; also an enema of sweet oil, soap and water. He passed slightly colored fluid with some little fecal matter and mucus. After this he had a small quantity of water by the mouth, and at 6.20 p. m. a nutritive enema of egg, whisky and water, which was partly retained. Digitalis and strychnin were both given during the evening.

At 9 p. m. the President was resting comfortably. The pulse was 130; temperature, 101.6°; respiration, 30.

Four hundred and twenty cc. of urine were passed during the day.

SECOND URINALYSIS.

Quantity..... 450 cc.
Color..... amber, slightly turbid
Reaction..... strongly acid
Specific gravity..... 1.026
Urea..... 0.938 gm. per 1 cc. of urine
Sugar..... none
Albumin..... mere trace
Indican..... abundant
Sulfates..... increased
Phosphates..... somewhat increased
Chlorids..... somewhat increased

Microscopic Examination.—Microscopic Examination of sediment obtained by centrifuge shows fewer organic elements. Some large and small epithelial cells and some leukocytes. Casts are not so abundant as yesterday and are principally of the small finely granular variety. There is a marked diminution in small renal epithelial cells.

Quite a quantity of large crystals of uric acid and bacteria are present.

FOURTH DAY, MONDAY, SEPTEMBER 9.

The bulletins tell the story of the fourth day.

Bulletin 15, 6 a. m.—The President passed a somewhat restless night, sleeping fairly well. General condition unchanged. Pulse, 120; temperature, 101°; respiration, 28.

Bulletin 18, 9.20 a. m.—The President's condition is becoming more and more satisfactory. Untoward incidents are less likely to occur. Pulse, 122; temperature, 100.8°; respiration, 28.

Bulletin 19, 3 p. m.—The President's condition steadily improves and he is comfortable, without pain or unfavorable symptoms. Bowel and kidney functions normally performed. Pulse, 113; temperature, 101°; respiration, 26.

Bulletin 20, 9.30 p. m.—The President's condition continues favorable. Pulse, 112; temperature, 101°; respiration, 27.

Codeia was substituted for morphin, as the pain was less. Digitalis and strychnin were stopped. Nutritive enemas were given at 3.20 a. m., at 4.30 and 10 p. m. Hot water was taken quite freely by the mouth.

Attempts to get a good movement of the bowels were successful at noon, when he had a large light-brown partly-formed stool. This followed a small dose of calomel and a high enema of oxgall.

On the whole, the President's condition improved steadily during the day. He slept a good deal and was fairly comfortable. There was no pain on pressure over the abdomen.

THIRD URINALYSIS.

Quantity received 540 cc.
 Color amber, slightly turbid
 Specific gravity 1.026
 Albumin a trace
 Indican not so abundant as yesterday
 Urea 0.047 gm. per cc. of urine
 Chlorids and phosphates about normal
 Sulfates still somewhat high
 Sugar none.

Microscopic Examination.—Microscopic Examination of sediment obtained by centrifuge shows a decrease in the amount of organic elements and an increase of amorphous urates, but fewer crystals of uric acid. Casts are fewer and only the small granular and large hyaline varieties. The proportion of casts is greater. There are very few epithelial cells, mostly of renal type. A large number of cylindroids is found.

FIFTH DAY, TUESDAY, SEPTEMBER 10.

Soon after the midnight the President had a high enema of soap and water, which was expelled, together with some fecal matter. He took hot water frequently, and slept a good deal.

Bulletin 21, 5.20 a. m.—The President has passed the most comfortable night since the attempt on his life. Pulse, 118; temperature, 100.4°; respiration, 28.

On awakening he felt very comfortable, and his mind was clear and cheerful. The nutritive enemata were kept up, and water given by the mouth. Had two small stools during the day. The only medicine given was one hypodermic of codeia phosphate, 0.015 gm.

In the evening the dressings were examined, and as there was considerable staining from the discharge, it was thought best to remove four stitches and separate the edges of the wound. A little slough was observed near the bullet track, covering a space nearly an inch wide, the thickness of the flaps. The separation seemed to extend down to the muscle. The surfaces, except those mentioned, looked healthy, but not granulating. It was supposed that the infection of the wound occurred either from the bullet or from the piece of clothing carried into the wound at the time of the shooting. The parts were thoroughly washed with hydrogen dioxid and packed lightly with gauze, held together with adhesive straps.

SIXTH DAY, WEDNESDAY, SEPTEMBER 11.

Bulletin 26, 9 a. m.—The President rested comfortably during the night. Decided benefit has followed the dressing of the wound made last night. His stomach tolerates the beef juice well, and it is taken with great satisfaction. His condition this morning is excellent. Pulse, 116; temperature, 100.2°.

Bulletin 27, 3.30 p. m.—The President continues to gain, and the wound is becoming more healthy. The nourishment taken into the stomach is being gradually increased. Pulse, 120; temperature, 100.2°.

Bulletin 28, 10 p. m.—The President's condition continues favorable. Blood count corroborates clinical evidence of the absence of any blood poisoning. He is able to take more nourishment and relish it. Pulse, 120; temperature, 100.4°.

The blood count made by Dr. Wasdin in the evening was as follows:

Leukocytes 6,752.
 Red cells 3,920,000

A little after midnight, Wednesday morning, the patient was given 4 cc. of beef juice, the first food taken by the stomach. It seemed to be very acceptable. Nutritive enema was given at 2 a. m.; later there was a yellow stool.

From 4 to 8 cc. of beef juice was given every one

to two hours during the day. The rectum was becoming irritable and did not retain the nutritive enemata well.

At 10 a. m. the remaining stitches were removed, the wound separated and dressed. It seemed to be doing well. Most of the sloughing tissue had separated.

The patient slept much during the day, and expressed himself as feeling very comfortable. The only medicine administered was one hypodermic of strychnin.

In the evening he was changed to a fresh bed. Nutritive enemata were continued.

Urine was passed much more freely—750 cc. in 24 hours.

FOURTH URINALYSIS

Quantity 82 cc.
 Color amber, clear
 Specific gravity 1.027
 Reaction strongly acid
 Albumin a trace
 Indican abundant
 Urea 0.04 gm. per 1 cc. of urine.
 E. phosphates and chlorids normal
 Sulfates still a little high

Microscopic Examination.—Microscopic Examination of sediment obtained by centrifuge, shows a marked diminution in amount of organic elements, but a great increase in uric acid crystals.

There are very few epithelial cells—mostly of renal type.

There are fewer casts—small and large hyaline—some finely granular.

Cylindroids are more abundant.

SEVENTH DAY, THURSDAY, SEPTEMBER 12.

The President slept a good deal during the night, and awoke in the morning feeling better. The beef juice was continued and increased, and a little chicken broth added to the dietary. He also had a little whiskey and water.

At 8.30 a. m. he had chicken broth, a very small piece of toast and a small cup of coffee. He did not care for the toast, and ate scarcely any of it.

The wound was dressed and washed with a weak solution of iodine and then with hydrogen dioxid. He was given 30 cc. of castor oil at 9.20 a. m.

The President now seemed at his best and his condition to warrant the favorable prognosis given out. The time for the peritonitis and sepsis had passed. The bowels had moved and gas passed freely, showing that there was no obstruction. The tongue was clear, and the appetite increasing; and he seemed to be able to digest food. There was no pain nor tenderness in the abdomen, and he was able to turn easily and to sleep on his side. The urine was steadily increasing. His spirits were good and his mind clear, while his pulse, though frequent, was strong and of good quality, and the temperature low.

The analysis of the urine gave no uneasiness, as the amount of urea was fair; there was no albumin worth considering, and the casts were rapidly diminishing. There were no more of them than are found in a large percentage of cases following a long operation under ether. The excess of indican was taken to mean merely some intestinal indigestion, and to be of no serious import. The only symptom to cause any uneasiness was the frequency of the pulse. Still, anxiety on this score was relieved by

knowing that the President had naturally a rapid pulse, and that it was easily excited. The open wound was not considered important. It looked healthy, and, although it would take a long time to heal, in itself it was evidently causing no harm, nor was it likely to.

Dr. McBurney left Buffalo for his home in the morning, having arranged to return at once if his presence was desired.

Toward noon it was noticed that the character of the pulse was not quite as good. Infusion of digitalis, 8 cc., was ordered, and strychnin, 0.002 gm.

It was thought probable that there was some intestinal toxemia, as there had been no free movement from the bowel since food had been begun, the oil having failed to act. Gradually the pulse went to 130, and grew weaker.

Dr. Charles G. Stockton was added to the medical staff in consultation. At 7 p. m. the President was given 0.20 gm. of calomel.

Bulletin 32, 8.30 p. m.—The President's condition this evening is not quite so good. His food has not agreed with him, and has been stopped. Excretion has not yet been properly established. The kidneys are acting well. His pulse is not satisfactory, but has improved in the last 2 hours. The wound is doing well. He is resting quietly. Temperature, 100.2°; pulse, 128.

At 9.30 p. m. a second dose of 30 cc. of castor oil was given, followed by a high enema of oxgall. This resulted in a large, dark semifluid stool, which seemed to exhaust him somewhat. Stimulants were given freely. No more beef juice or food was given. The pulse grew rapidly worse, but at midnight there seemed some improvement, as bulletin 33 shows. At 11 p. m. 420 cc. of normal salt solution was given subcutaneously.

Bulletin 33, 12 m.—All unfavorable symptoms in the President's condition have improved since the last bulletin. Pulse, 120; temperature, 100.2°.

FIFTH URINALYSIS.

Quantity 132 cc.
Color light amber, very turbid
Specific gravity 1.025
Reaction acid
Albumin mere trace, if any
Indican less
Urea 0.044 gm. per 1 cc. of urine
Sulfates about normal
E. phosphates much increased
Chlorids normal

Microscopic Examination.—Microscopic examination of sediment obtained by centrifuge, shows fewer organic elements than the last examination. There is less uric acid and a large amount of amorphous phosphates. Renal casts, about as in the last examination, with very few cylindroids.

EIGHTH DAY, FRIDAY, SEPTEMBER 13.

At midnight the pulse was fairly good, 132. Strychnin and whisky were given at intervals, and hypodermics of camphorated oil.

Bulletin 34, 2.50 a. m.—The President's condition is very serious, and gives rise to the gravest apprehension. His bowels have moved well, but his heart does not respond properly to stimulation. He is conscious. The skin is warm, and the pulse small, regular, easily compressible. 126; respiration, 30; temperature, 100.

The wound had been dressed regularly in the manner described three times a day. At 9 A. M. the dressing was changed, and a mixture of balsam of Peru and glycerin put in on gauze after the douching.

Stimulants were continued as before, but more

freely. Coffee, 45 cc., and clam broth, 60 cc., were given; also liquid peptonoids.

At 8.30 1.50 gm. of adrenalin was given hypodermically, and repeated at 9.40.

At 10 A. M. nearly two pints of normal salt solution were given under the skin, and a pint containing adrenalin at 6 P. M. Nitroglycerin and camphor were also injected at various times, together with brandy and strychnin.

Stimulants as detailed above were used freely all day.

3.30 P. M. Pulse growing weaker.

5.00 P. M. Oxygen given and continued for some hours.

6.30 P. M. Last bulletin, No. 39:

Bulletin 39, 6.30 p. m.—The President's physicians report that his condition is most serious in spite of vigorous stimulation. The depression continues and is profound. Unless it can be relieved, the end is only a question of time.

At 6.35 P. M., and again at 7.40, morphin was given hypodermically, as he was very restless and seemed to be suffering.

9.00 P. M. Heart sounds very feeble.

The President continued to sink, becoming weaker and weaker.

At 10 P. M. the oxygen was discontinued. The heart sounds were very feeble and consciousness lost.

The President died at 2.15 A. M., September 14.

Drs. E. J. Janeway and W. W. Johnston, who, at the request of Dr. Rixey, had been summoned in consultation, arrived too late, but were present at the autopsy. Dr. McBurney also returned on Friday afternoon.

SIXTH URINALYSIS.

Color amber, turbid, with phosphates
Quantity 252 cc.
Reaction acid
Specific gravity 1.023
Albumin mere trace, if any
Urea 0.017 gm. per 1 cc. urine
Indican a trace
E. phosphates increased
Chlorids normal
Sulfates a little high

Microscopic Examination.—Microscopic examination of sediment obtained by centrifuge, before and after clearing, shows no change from yesterday's sample. Casts, hyaline and granular, both large and small, comparatively few. Cylindroids, a few. Crystals, large amount of uric acid, some sodium urate, and in the untreated specimen a large amount of amorphous deposit, principally of phosphates. There are a few epithelial cells, small, granular. Occasional red cells and leukocytes.

REPORT ON THE AUTOPSY.

By

HARVEY R. GAYLORD, M. D.,

Pathologist to the New York State Pathological Laboratory.

Ordinary signs of death: ecchymosis in dependent portions of the body. Rigor mortis well marked. Upon the surface of the chest, to the right of the midsternal line, a spot 1 cm. in diameter, dark-red in color, with a slight crust formation covering it, 5.5 cm. from the suprasternal notch; from the right nipple, 10 cm.; from the line of the right nipple, 8.25 cm. Surrounding this spot, at which point there is an evident dissection of the

¹The autopsy was performed by Drs. Gaylord and Matzinger.

continuity of the skin, is a discolored area of oval shape extending upward and to the right. In its greatest length it is 11 cm.; and in its greatest width, 6 cm. It extends upward in the direction of the right shoulder. The skin within this area is discolored, greenish-yellow and mottled.

The surface of the abdomen is covered with a surgical dressing, which extends down to the umbilicus and upward to just below the nipples. The innermost layer of cotton is covered or stained with balsam of Peru and blood. On removing this dressing, a wound, parallel to, and somewhat to the left of the median line, is exposed, inserted in which are 2 layers of gauze, likewise impregnated with balsam of Peru. The wound is 14.5 cm. in length, and is open down to the abdominal muscles. The layer of abdominal fat is 3.75 cm. in thickness. The appearance of the fat is good, a bright yellow in color. No evidence of necrosis or sloughing. In the left margin of the surgical wound, lying 1 cm. to the right of a line drawn from the umbilicus to the left nipple, 15.5 cm. from the nipple and 16.5 cm. from the umbilicus is a partly healed indentation of the skin, and an excavation of the fat immediately beneath it (this is the site of the entry of the bullet), extending down to the peritoneal surface. On making the median incision, starting from the suprasternal notch and extending to a point just below the symphysis, the subcutaneous fat is exposed, which is of bright yellow color and normal appearance except in an area which corresponds superficially to the area of discoloration described as surrounding the wound upon the chest wall. This area marks the site of a hemorrhage into the subcutaneous fat. The remainder of the subcutaneous fat is firm and measures 4.75 cm. in thickness on the abdominal wall. On opening the sheath of the right rectus muscle, it is seen to be of dark-red color. (Culture taken from ecchymotic tissue under the upper bullet hole and from between the folds of the small intestines. Three tubes from each locality on agar and gelatin.)

On opening the abdominal cavity, the parietal surface of the peritoneum is exposed, and is found to be covered with a slight amount of bloody fluid; is perfectly smooth and not injected. The great omentum extends downward to a point midway between the umbilicus and the symphysis. It is thick, firm; its inferior border is discolored by coming in contact with the intestines. Below the umbilicus a few folds of intestines are exposed. These are likewise covered with discolored blood, after the removal of which the peritoneal surface is found to be shiny. On the inner aspect of the abdominal wound the omentum is found to

be slightly adherent to the parietal peritoneum, and can be readily separated with the hand from the edge of the wound. At this point the omentum is somewhat injected. This adhesion to the omentum is found to extend entirely around the abdominal wound. The parietal peritoneum immediately adjacent to the inner aspect of the abdominal wound is ecchymotic.

On removing the subcutaneous fat and muscles from the thoracic wall, the point which marks the dissolution of continuity of the skin upon the surface, is found to lie directly over the margin of the sternum and to the right side between the second and third ribs. There is no evidence of ecchymosis or injury to the tissues or muscles beneath the subcutaneous fat. On making an incision through the subcutaneous fat, directly through the wound upon the chest, a small cavity is exposed about the size of a pea just beneath the skin which is filled with fluid blood. The subcutaneous tissue underlying the area of discoloration on the surface of the chest wall shows hemorrhagic infiltration.

On removing the sternum, the lungs are exposed, and do not extend far forward. A large amount of pericardial fat is exposed. Pleural surface on both sides is smooth. There are no adhesions on either side within the pleural cavities. The diaphragm on the right side extends upward to a point opposite the third rib in the mammary line. No perceptible amount of fluid in either pleural cavity. On opening the pericardial cavity, the surface of the pericardium is found to be smooth and pale. The pericardium contains approximately 6 cc. of straw-colored, slightly turbid fluid. (Some taken for examination.)

On exposing the heart, it is found covered with a well-developed panniculus. The heart measures, from the base to the apex, on the superficial aspect, 10.5 cm. The right ventricle is apparently empty. The heart feels soft and flaccid. On opening the left ventricle, a small amount of dark-red blood is found. The muscle of the left ventricular wall is 1.5 cm. in thickness; dark reddish-brown in color; presents a shiny surface. The average thickness of the pericardial fat is 3.5 mm. (Cultures made from the auricle.) The left auricle contains but a small amount of dark currant-colored blood. The mitral valve admits 3 fingers. The right ventricle, when incised in the anterior line, is found to be extremely soft; the muscular structure is 2 mm. in thickness. The panniculus measures 7 mm. The muscle is dark red in color; very shiny, and the pericardial fat invades the muscular wall at many points.

On opening the right auricle it is found to be filled and

distended by a large currant-colored clot, which extends into the vessels. The tricuspid orifice readily admits 3 fingers. The coronary arteries are patulous and soft; no evidence of thickening.

Lungs are gray color, and contain a moderate amount of coal-dust pigment. Slight amount of frothy fluid escapes from the bronchi; but the pulmonary tissue is crepitant and free from exudate.

On unfolding the folds of intestine, there is no evidence of adhesion until a point just beneath the mesocolon is reached, when, on removing a fold of small intestine, a few spoonfuls of greenish-gray thick fluid flow into the peritoneal cavity.

On the anterior gastric wall is an area to which a fold of the gastrocolic omentum is lightly adherent. On breaking the adhesion there is found a wound about midway between the gastric orifices, 3.5 cm. in length, parallel with the greater curvature of the stomach, 1.5 cm. from the line of omental attachment. This wound is held intact by silk sutures. There is no evidence of adhesion at any other point on the anterior wall. The gastric wall surrounding the wound just mentioned for a distance of 2 cm. to 3 cm. is discolored, dark greenish-gray in appearance, and easily torn. On exposing the posterior wall of the stomach from above, along its greater curvature, the omentum is found to be slightly adherent, a line of silk ligatures along the greater curvature of the stomach marking the site where the omentum had been removed. On throwing the omentum downward, the posterior gastric wall is exposed. On the posterior wall, a distance of 2 cm. from the line of omental attachment, is a wound approximately 2 cm. long, held intact by silk sutures. The gastric wall surrounding this wound is discolored. On the surface of the mesocolon, which is posterior to the gastric wall at this point, is a corresponding area of discoloration, the portion coming directly in contact with the wound in the gastric wall being of dull gray color. The remainder of the surface of the posterior wall of the stomach is smooth and shiny. Beyond the surgical wound in the posterior wall of the stomach is found an opening in the retroperitoneal fat, large enough to admit 2 fingers. This opening communicates with a track which extends downward and backward as far as the finger can reach. The tissues surrounding this track are necrotic. On removing the descending portion of the colon, a large irregular cavity is exposed, the walls of which are covered with gray, slimy material, and in which are found fragments of necrotic tissue. Just at the superior margin of the kidney is located a definite opening which forms the bottom of the track traced from the stomach. On stripping the left kidney from its capsule, it is found that the superior portion of the capsule is continuous with the cavity. The weight of the left kidney is 5 oz. 1 grain. The kidney is readily stripped from its capsule; is dark red; the stellate veins are prominent, and along its greater curvature are numerous dark red depressions. On the superior aspect of the kidney is a protrusion of the cortex, dark red in color, and in this protrusion is a laceration 2 cm. long, extending across the superior border, approximately at right angles to the periphery of the kidney and from before backward. On incising the kidney, the cortex and medulla are not easily distinguishable from one another; both are of rose-red color, the cortex measuring approximately 6 mm. in thickness. The vessels in the pyramids of Ferrein are very prominent. Beneath the protruding portion of the surface, the cortex is dark red in color. This discoloration extends downward in pyramidal form into the medulla. The laceration of the surface marks the apex of the protrusion of the kidney substance. Between the spleen and the superior aspect of the kidney is a necrotic tract which extends down and backward, and ends in a blind pocket. The tract, which included the superior aspect of the kidney, can be traced into the perinephritic fat to a point just above the surface of the muscles of the back.

The necrotic cavity which connects the wound on the posterior wall of the stomach and the opening adjacent to the kidney capsule is walled off by the mesocolon, and is found to involve an area of the pancreas, approximately 15 mm. in diameter and extending about half-through the organ. This organ at its center forms part of the necrotic cavity. Through its body are found numerous minute hemorrhages and areas of gray softening, the size of a pea or smaller. These are less frequent in the head portion of the pancreas.

A careful examination of the track leading down toward the dorsal muscles fails to reveal the presence of any foreign body. After passing into the fat, the direct character of the track ceases; and its direction can be traced no further. The adjoining fat and the muscles of the back were carefully palpated and incised, without disclosing a wound or the presence of a foreign body. The diaphragm was carefully dissected away, and the posterior portion of the thoracic wall likewise carefully examined. All fat and organs which were removed, including the intestines, were likewise examined and palpated, without result.

The great amount of fat in the abdominal cavity, and surrounding the kidney rendered the search extremely difficult.

The right kidney is imbedded in a dense mass of fat; capsule strips freely; it weighs 5 ounces; measures 11.5 cm.; substance is soft; cortex is 6 mm. in thickness; rose-red in color; cut surface slightly dulled. There are a few depressions of the surface, and the stellate veins are prominent.

The liver is dark-red in color; the gallbladder distended. The organ was not removed.

The autopsy continued for a longer period than was anticipated by those who had charge of the President's body, and we were requested to desist seeking for the bullet and terminate the autopsy. As we were satisfied that nothing could be gained by locating the bullet, which had apparently set up no reaction, search for it was discontinued.

Anatomic Diagnosis.—Gunshot wound of both walls of the stomach and the superior aspect of the left kidney; extensive necrosis of the substance of the pancreas; necrosis of the gastric wall in the neighborhood of both wounds; fatty degeneration, infiltration and brown atrophy of the heart muscle; slight cloudy swelling of the epithelium of the kidneys.

A matter of no inconsiderable embarrassment to us arose in the objection to our removing sufficient portions of the tissues for examination. We were able to secure only 2 small fragments of the stomach wall; tissue from around the wound upon the chest wall; a portion of fat from the wall of the necrotic cavity; a small piece of each kidney, that of the left kidney including the portion involved by the original wound; and pieces of heart-muscle from the right and left ventricles. The microscopic examination of these tissues follows:

The piece of retroperitoneal fat, where it forms part of the necrotic cavity, is seen on section to be covered with a thick gray deposit, which has an average thickness of from 4 mm. to 6 mm. Beneath this, and separating it from the fat, is a well-defined area of hemorrhage from 1 mm. to 2 mm. in thickness. The appearance of this piece of tissue is characteristic of the fat tissue surrounding the entire cavity. A section made perpendicular to the surface and stained with hematoxylin-eosin, shows the following characteristics: Under low power there is no evidence of round-celled infiltration between the fat cells, or of fat necroses. The surface of the tissue which, in the microscopic specimen was covered by a layer of grayish material, proves, under low power, to consist of a partly organized fibrinous deposit. At the base of this deposit is evidence of an extensive hemorrhage, marked by deposits of pigment. The surface of the membrane is of rough and irregular appearance, and contains a large number of round cells with deeply stained nuclei. Under high power the organization of the membrane may be traced from the base toward the surface. The portion immediately adjacent to the fat tissue consists of a network of fibrin enclosing large numbers of partly preserved red blood corpuscles. In many areas the red blood corpuscles are broken down and extensive deposits of pigment are found. Extending into the fibrin structure of the membrane are numerous typical fibroblasts and round cells. In some regions pigment is evidently deposited in the bodies of large branching and spindle cells. Here and there, included in the membrane, are the remains of fat cells, and toward the surface of the membrane a large number of round cells scattered through the interstices of the membrane. There are but few polymorphonuclear leucocytes. Here and there in the membrane are fragments of isolated fibrous connective tissue with irregular contours and an appearance suggesting that they are frag-

ments of tissue which have been displaced by violence and included in the fibrin deposit. The fibrin in the superficial layers of the membrane is formed in hyaline clumps. The organization along the base of the deposit is comparatively uniform.

Sections stained with methylen blue, carbol-thionin and Gram's method were carefully examined for the presence of bacteria, with negative results. Even upon the surface of the membrane there are no evidences of bacteria.

The section of the left kidney including the triangular area of hemorrhage described in the macroscopic specimen, reveals the following appearances. (Section hardened in formalin, stained with hematoxylin-eosin.) Examined macroscopically, section represents a portion of a kidney cortex made perpendicular to the surface of the cortex, and including an area of hemorrhage into the substance of the cortex 1 cm. in length, measured from the capsular surface downward, and presenting a width of from 5 mm. to 6 mm. The capsular surface has apparently been torn.

Under low power the margins of the preparation are found to consist of well preserved kidney structure. There is a slight amount of thickening of the interstitial tissue, and occasional groups of tubules are affected by beginning cloudy swelling. The glomeruli are large and present a perfectly normal appearance. As we approach toward the center of the preparation, occasional glomeruli are met with in which the capillary loops are engorged and the adjacent tubules contain red blood-corpuscles. A short distance further, the kidney structure becomes entirely necrotic. Here and there the remains of tubules may be made out, and these are infiltrated with cells. The necrotic area presents a rough, net-like structure. As we approach toward the surface of the kidney, we find that the necrosis becomes more marked. There is the merest suggestion of kidney structure, its place being taken by disintegrated red blood-cells and leukocytes, embedded in a well-defined fibrinous network. There is great distortion of the kidney structure about the periphery of the necrotic area. In this region a considerable amount of pigment is also found in the necrotic tissues.

Under high power, the characteristics of the necrotic tissues may be better observed. The kidney structure is broken up and torn into irregular fragments, infiltrated by red blood corpuscles and leukocytes. In the portion of the necrotic mass beneath the capsule, the kidney structure is practically obliterated and is replaced by a network of fibrin, which includes large numbers of red blood-cells and leukocytes. Scattered through the entire necrotic area are frequent deposits of pigment. In the deeper portions of the necrotic area, the margins of the fibrin deposit are invaded by fibroblasts from the connective tissue of the kidney. The organization in these areas is, however, slight.

Sections stained with methylen-blue and Gram's method and carefully examined under oil immersion, fail to reveal the presence of any organisms. In preparations stained with methylen blue, the deposits of pigment may be readily observed. Section of the same tissue hardened in Hermann's solution and examined for fat, shows the presence of numerous fat droplets within the epithelium of the tubules which are adjacent to the area of necrosis. In the portions of the preparation more widely distant from the area of necrosis, no fat is present.

Section of the right kidney hardened in formalin and stained with hematoxylin-eosin, reveals the presence of areas in which slight parenchymatous degeneration of the epithelium in the uriniferous tubules may be noted. These areas are not extensive, and are confined to single groups of tubules. The interstitial connective tissue of the organ seems to be slightly increased in amount, but there is no well-defined round-celled infiltration. An occasional hyaline glomerulus is to be met with in these cases surrounded by increased connective tissue. The epithelium of the kidney tubules, aside from those in which the parenchymatous degeneration is present, is well preserved. The nuclei are well stained; protoplasm, finely granular.

A fragment of the stomach wall taken from the immediate neighborhood of the anterior wound is in a condition of complete necrosis. The nuclei of the cells are scarcely demonstrable. The epithelial surface is recognized with difficulty. At its base are apparently a few round cells. Examination of the bloodvessels reveals nothing characteristic. There is apparently no evidence of thrombosis.

A section made through the gastric wall at some distance from the wound, reveals the well-preserved muscular structure of the gastric wall, which presents no characteristic alterations. Superficial portions of the epithelium have apparently been affected by postmortem digestion. However, in one portion of the preparation, the epithelium is intact, and shows distinct evidence of marked round-celled infiltration between the glandular structures. The bloodvessels contained blood-corpuscles with the usual number of leukocytes.

The fragments of heart-muscle which were removed from the right and left ventricular walls, were examined in the fresh state, and exhibited a well-defined fatty degeneration of the muscle fibres, and in the case of the right ventricular wall, an extensive infiltration between the muscle fibers, of fat, was apparent. Sections from these fragments of muscle hardened in Hermann's solution, are taken for examination. A fragment of muscle from the right ventricular wall was removed at a point where the fat penetrated deeply into the muscular structure, the ventricular wall at this point showing an average thickness of 2.5 mm. Under low power, the muscle fibers are separated into bundles by masses and rows of deeply stained fat cells. The muscle fibers are seen to contain groups of dark brown granules lying in the long axes of the cells. Under high power, these are resolved into extensive groups of dark brown pigment arranged around the nuclei. The muscle fibers are slender, the cross and longitudinal striation is well-defined. Examination near the margin of the preparation, where the osmic-acid fixation has been successful, all of the muscle fibers are found to contain black spherical bodies, extending diffusely through all the muscle fibres about the entire margin of the preparation. These fine fat droplets are present in sufficient amount to speak of an extensive diffuse fatty degeneration of the muscle fibers. Where the large fat cells have separated the muscle fibers, these are found to be more atrophic than those in the central portions of the larger bundles.

The examination of the section through the healed bullet wound on the chest walls reveals nothing of importance. The dissolution of continuity is filled in by granulation-tissue, and there is evidence of beginning restoration of the epithelium from the margins. Stains for bacteria give negative results.

In Summing up the macroscopic and microscopic findings of the autopsy, the following may be stated: The original injuries to the stomach-wall had been repaired by suture, and this repair seems to have been effective. The stitches were in place, and the openings in the stomach-wall were effectually closed. Firm adhesions were formed both upon the anterior and posterior walls of the stomach, which reinforced these sutures. The necroses surrounding the wounds in the stomach do not seem to be the result of any well-defined cause. It is highly probable that they were practically terminal in their nature, and that the condition developed as a result of lowered vitality. In this connection there is no evidence to indicate that the removal of the omentum from the greater curvature and the close proximity of both of these wounds to this point, had any effect in bringing about the necrosis of the gastric wall, although circulatory disturbances may have been a factor. The fact that the necrotic tissue had not been affected by digestion strongly indicates that the necrosis was developed but shortly before death. The excavation in the fat behind the stomach must be largely attributed to the action of the missile. This may have been the result of unusual rotation of a nearly spent ball, or the result of simple concussion from the ball passing into a mass of soft tissues. Such effects are not unknown. The fact that the ball grazed the superior aspect of the left kidney, shown by the microscopic investigation of that organ, indicates the direction of the missile, which passed in a line from the in-

ferior border of the stomach to the tract in the fat immediately superior to the kidney. There was evidence that the left adrenal gland was injured.

The injury to the pancreas must be attributed to indirect, rather than direct, action of the missile. The fact that the wall of the cavity is lined by fibrin, well advanced in organization, indicates that the injury to the tissues was produced at the time of the shooting. The absence of bacteria from the tissues, indicates that the wound was not infected at the time of the shooting, and that the closure of the posterior gastric wound was effectual. The necrosis of the pancreas seems to us of great importance. The fact that there were no fat necroses in the neighborhood of this organ, indicates that there was no leakage of pancreatic fluid into the surrounding tissues. It is possible that there was a leakage of pancreatic fluid into the cavity behind the stomach, as the contents of this cavity consisted of a thick, grayish fluid, containing fragments of connective tissue. In this case the wall of fibrin would have been sufficient to prevent the pancreatic fluid from coming in contact with the adjacent fat. The extensive necrosis of the pancreas would seem to be an important factor in the cause of death, although it has never been definitely shown how much destruction of this organ is necessary to produce death. There are experiments upon animals upon record, in which the animals seem to have died as a result of not very extensive lesions of this organ. One experiment of this nature reported by Flexner (*Journal of Experimental Medicine*, Vol. II) is of interest. The fact that concussion and slight injuries of the pancreas may be a factor in the development of necrosis, is indicated by the researches of Chiari (*Zeitschrift für Heilkunde*, Vol. XVII, 1896, and *Prager Med. Wochenschr.*, 1900, No. 14), who has observed (although a comparatively rare condition) extensive areas of softening and necrosis of the pancreas, especially of the posterior central portion which lies directly over the bodies of the vertebra, where the organ is most exposed to pressure or the effects of concussion. The wound in the kidney is of slight importance, except as indicating the direction taken by the missile. The changes in the heart, as shown by the macroscopic inspection and the microscopic examination, indicate that the condition of this organ was an important factor. The extensive brown atrophy and diffuse fatty degeneration of the muscle, but especially the extent to which the pericardial fat had invaded the atrophic muscle fibres of the right ventricular wall, sufficiently explain the rapid pulse and lack of response of this organ to stimulation during life.

REPORT ON THE BACTERIOLOGIC EXAMINATION.

By

HERMAN G. MATZINGER, M. D.,

Bacteriologist to the New York State Pathological Laboratory.

It is obvious that the short space of time which has elapsed since the death of the President has hardly been sufficient to prepare a complete and thorough bacteriologic report. This report contains all the observations which have been made up to this time:

On September 11, during the life of the President, cultures were made by Dr. Wasdin from the base of the ab-

dominal wound and from dressings removed at the same time. These were submitted to me for examination, and showed the presence of the ordinary pus organisms: staphylococcus pyogenes aureus and s. cereus albus with a gas-forming bacillus which, in pure anaerobic culture on glucose gelatin, forms small, pearly, translucent colonies, with no liquefaction. In litmus milk it produces acid, but no coagulation. Morphologically, it is apparently a capsulated, short bacillus, which takes stains poorly, and which does not stain by Gram's method. Inoculated into the ear vein of a rabbit, which was killed immediately afterward, it produced, after 24 hours in the body of the rabbit, a marked accumulation of gas in the organs, and again grew out in pure culture. As yet the organism is not fully identified.

None of these cultures showed streptococci. A bacterium which appears to be one of the proteus group was, however, isolated, which does not stain by Gram, and appears in varying forms, sometimes small oval, and again quite rod-shaped and in short chains. Sometimes it is surrounded with a slimy covering, which remains clear like a capsule when the organism is stained. On slanting agar, it produces a whitish, slimy growth, which gradually runs to the bottom of the slant and produces an odor of decomposition. On gelatin, it grows very slowly with slight and slow indication of liquefaction. In litmus milk, it produces acid and rapid coagulation.

At the time of the autopsy, September 14, inoculations were made by myself. From the base of the wound, there was again obtained a number of pus organisms, principally a white staphylococcus and the bacterium described above, but no streptococci. Cultures made from the peritoneal surface of the intestines were entirely negative. Cultures made from the under surface of the omentum near the colon, were entirely negative, both with and without oxygen. Cultures from the blood of the right auricle were likewise negative. A very careful and extensive search for microorganism in the contents of the necrotic cavity, behind the stomach, reveals nothing but a short stumpy bacterium, which, as far as the work has been carried at present, appears to belong to the proteus group, and is very like proteus hominis capsulatus, described by Bordoni and Uffreduzzi.

Morphologically, it is not uniform, and sometimes appears almost encapsulated, being surrounded by material that does not stain; is quite refractory to Gram, and produces an odor of decomposition as it grows. It does not liquefy gelatin rapidly and grows slowly, as a glistening white elevated surface growth which slowly sinks; but on agar in the thermostat it grows very rapidly, as a moist, grayish-white, translucent mass. Colonies on gelatin plates have a clean circumference, are granular and quite refractive. In litmus milk it produces acid and rapid coagulation. Animal experiments are still incomplete and cannot be published at this time.

It must be stated that there is occasion for suspecting that this may be a contamination, either from the outer wound or elsewhere, because, quite unavoidably, the technique of obtaining the material and cultures from the necrotic cavity was not absolutely correct.

Cultures made from the small area of broken-down tissue under the chest wound at the time of the autopsy, grew what appears to be staphylococcus epidermidis albus, described by Dr. Welch.

The slimy, gray, necrotic material from the cavity above the transverse mesocolon behind the stomach, was carefully examined microscopically, with the result that very few micro-organisms were found in the fresh state, and no recognizable tissue elements of any kind, no leukocytes nor pus-corpuscles, but an abundance of crystals which appeared more like fatty acid than fat crystals. It contained no free hydrochloric acid, and was alkaline in reaction. Experiments as to its digestive power were negative. About 2 cc. of this material were injected into the space behind the stomach of a dog (still living), with no results except an elevated temperature for 3 or 4 days. Other animal experiments are also still incomplete.

It might be well to state here that the bacteriologic examination of the chambers and barrel of the weapon used, as well as the empty shells and cartridges, ordered by the District Attorney, was entirely negative, except that from a loaded cartridge

there was grown an ordinary staphylococcus and a mould. The chemical examination of the balance of the loaded cartridges, made by Dr. Hill, chemist, was also negative.

The absence of known pathogenic bacteria, particularly in the necrotic cavity, warrants the conclusion that bacterial infection was not a factor in the production of the conditions found at autopsy.

A SYMPOSIUM ON THE CZOLGOSZ CASE.

THE TRIAL OF CZOLGOSZ.

By GEORGE S. GRAHAM, ESQ.

Former District Attorney of Philadelphia.

To the Editor of *The Philadelphia Medical Journal*:

I have read with interest your two editorials in the issue of your paper of October 5th; one on the Czolgosz trial, and the other on Erskine's defence of Hadfield. Erskine is deserving of all your praise. Likewise, if the fact be true that the counsel for Czolgosz believed him to be insane, and so expressed themselves, and could have produced evidence tending to show insanity, then your criticism of them is equally just and your temperate comment fully justified.

I have not, myself, seen any published statement of the belief of the prisoner's counsel in his insanity. From the high standing and character of those gentlemen I would prefer to believe they had not made such statements, without indubitable proof to sustain such a belief.

In every criminal trial the presumption of sanity, like that of innocence, stands until the presumption is overcome by evidence. In the trial of Czolgosz there was not a scintilla of evidence upon which to base an argument supporting a theory of insanity. Upon the evidence adduced the verdict of guilty was eminently proper and thoroughly just. So that from the trial itself there was no ground for expressing such a belief as that referred to.

Drs. Allan McLane Hamilton, Carlos T. MacDonald and others who, as alienists, examined the prisoner with the view of ascertaining his mental condition, pronounced him sane. Unless therefore the counsel for the prisoner had or knew of alienists who had come to a contrary opinion, there was no medical testimony on which to base such a view.

If the counsel had medical testimony tending to prove sanity, and did not submit it to the jury, then they were unfaithful to the court, the prisoner and their own oaths as sworn officers of the court. I am sure that this cannot be true, and would infer from the course of the trial that they were powerless to procure such evidence. Under these circumstances they would have no right to present their individual belief of insanity (if they held such a belief) to the jury, and their conduct of the case would be free from criticism for not doing so. The statement of their belief would be inadmissible as evidence, and when unsupported by testimony would be improper as part of the address to the jury. Counsel have no right to address a jury upon views or matters not presented in the evidence or fairly deducible therefrom.

Erskine had a client whose cause had some merit;

whose wounds received in his country's service pleaded for him; and, also, *had evidence* tending to prove insanity. His eloquent plea on that ground was appropriate and based on proof. There was neither merit nor evidence to sustain such an appeal in the Czolgosz case.

The expression of an individual opinion by counsel after the trial, relative to a belief in the prisoner's insanity, is a question which addresses itself to the forum of the individual's conscience and is not debatable as an incident of the trial, and stands outside the pale of medical jurisprudence. The propriety and good taste of such an expression of belief, is alone for the individual. He has the undoubted right to utter it, or leave it unsaid. If the report of the statement by counsel be true, I agree with you that they "have rather spoiled a fine situation by speaking as they did out of court."

(Note by the Editor:—The statement, after the trial, by the counsel for the assassin that they believed him to be insane, was published by several newspapers. We have never seen its authenticity denied, nor have we seen a denial by the eminent counsel that they entertained this opinion. We shall be only too happy to correct the statement, if it is spurious).

THE CRIME OF CZOLGOSZ, THE ASSASSIN.

By JOHN B. CHAPIN, M. D., of Philadelphia.

Superintendent of Pennsylvania Hospital for Insane.

To the Editor of the *Philadelphia Medical Journal*:

1. The shock and depression that affected not only our own country but the people of all lands, on the occasion of the murderous assault upon President McKinley, are still vividly recalled. Following this event there has succeeded a profound sense of injury and unforgiveness of the adherents of the pernicious dogmas that are believed to have led up to this national calamity. While the issues of life seemed in the balance there was profound thankfulness that in the momentous emergency the surgeons who were summoned courageously assumed grave responsibilities and performed every known service in the present state of science. It is a satisfaction and a subject of congratulation that the greatest surgical authorities of the world, as well as the people at large, were in daily touch with the condition of the distinguished sufferer and have approved of the management of the case. The conferences of the surgeons appear to have been harmonious. They showed a sense of the solemn responsibilities resting upon them. They demonstrated as well the wonderful possibilities as the limitations of modern surgical science and knowledge, and when all has been well done there is little room and less need for indecorous, unseemly, pessimistic criticism.

2. The death of the President, the arrest of the assassin, his trial, conviction and sentence, which followed with commendable but orderly promptness, are notable events which might not warrant a notice in a medical journal but for some of the lessons and precedents that were made. In the practice of law, and in court proceedings, there seems at times such a fetish reverence for precedents that the main issue is clouded and even lost to sight. For a time there was an apprehension such would be the

outcome of the trial of the assassin. Here was the case of a man committing a homicide under most aggravating circumstances. The Chief Magistrate of our nation was shot and killed by an assassin while in the discharge of a most gracious public function, by a man unknown to him or to the locality, who in subsequent conversation avowed himself to be an anarchist. He alleged that the act was committed from a sense of "duty," that he had no personal grievance, but he was opposed to the Government of which the President was the head. His motive was the destruction of the Government by removing the President. He stated the crime was not the outcome of a conspiracy, that no one had designated him to be an instrument, and that he alone carried the plan into execution, an opportunity for doing which he had looked for several days. He stated also that he had been influenced by reading and listening to lectures or harangues to perform his murderous act.

This is the first assassination in our country that is to be traced to avowed ideas and organizations for the purpose of destroying the Government by killing his officers, because they stand for tyranny and the financial distress of the poor. This fact together with the enormity of the crime would in our country at once suggest that insanity would and ought to be interposed as a defence. It is a common hypothesis, and too frequently put forward, that an awful tragedy must be the act of a diseased mind. In this case, however, the trial reports published in newspapers state that a new precedent has been created which may be studied in the interests of justice and protection against criminals. It is reported that with the concurrence of the Bar Association of Buffalo, and on invitation of District Attorney Penney, Drs. Hurd, of Buffalo, and Carlos F. MacDonald, of New York, and several physicians of Buffalo, made an examination and reported the assassin to be sane. This opinion of competent experts eliminated a plea of insanity from the whole proceedings, leaving the guilt or innocence as the only issue to be tried, and no defence was offered, as there was none to present. The allegation alone that the act was performed from a sense of "duty" unaccompanied by other symptoms was not in itself a delusion in a medical or legal sense to excuse a criminal act any more than other erroneous beliefs or opinions on similar grounds. The delusions of the insane are the outcome, and imply the existence of a diseased mind, and result wholly from that condition, otherwise any criminal might plead that he committed crime from a sense of duty. Erroneous, mistaken notions do not come within the category of symptoms of insanity. To admit them for a moment would broaden the field of inquiry indefinitely. Neither could the plea of "irresistible impulse" avail, for the assassin took much time to deliberate. It is true that impulses to criminal acts are not resisted when they might and ought to be, and this fact is often the very essence of criminal intent. As the experts did not have an opportunity to present in court the reasons for their conclusions, we may look for some public expression of their own views hereafter. Neither in the portraits of the assassin do we note any marked sign of "degeneration," and the cranial

development appears to be normal. There only remains room for psychological speculation and theorizing. The management and medico-legal proceeding in this case are commended as suggestive that a new precedent and departure in insanity trials have been made.

It is quite a common experience that only an imperfect, insufficient history can be obtained of obscure, unsettled persons in the social scale in which Czolgosz moved, but if the statement which has been published comprises the whole case, supplemented by what the experts acquired by personal examination, their conclusions were absolutely correct, and the verdict was the only result to be reached.

3. The problem of the disposition to be made of professional Government wreckers by assassination is a more serious one. It may be difficult to frame a legal definition of the crime of entertaining anarchistic doctrines, but the danger that may come from publishing, proclaiming and encouraging violent measures intended to overthrow the Government by the commission of murder is quite another matter. Organized society must first protect itself at all hazards, and by extraordinary measures. No one questions the use of extraordinary measures to preserve the public health against danger from contagious disease. Society and self-protection sanction even the destruction of well-recognized pest centres, suspected persons and cases are carefully guarded until all danger is passed. The professional anarchist and his doctrines and other ranters are far more dangerous and pernicious moral pests, because the culture field is more abundant and diffused in the undesirable emigration that has already gained an entrance into the country. If it be made legal to deport the dangerous professional anarchist who has applied for entrance into our ports, it may be made legal on trial to isolate and deport those already here until their ferocious natures are subdued by education, the diffusion of knowledge and the inculcation of loftier moral principles. If perchance collected on some island, they might dwell together in love like the Arcadian farmers of Longfellow. They might there perchance enjoy the compulsory opportunity of self-support. As there would be no government probable, human life might be safer, as there would be no king, or president, or ruler to assassinate. Under any circumstances the whole subject may be properly relegated where responsibility and power are vested.

THE OPINION OF AN EXPERT WHO EXAMINED CZOLGOSZ.

By JAMES W. PUTNAM, M. D., of Buffalo, N. Y.

To the Editor of the *Philadelphia Medical Journal*:

The trial of Czolgosz is over and the jury has returned a verdict of guilty in the first degree. To those familiar with the crime and the assassin, no other verdict was expected. The trial was unusual in this respect that no possible defence was found. The prisoner was represented by able counsel chosen for the purpose by the Erie County Bar Association. They engaged, by the advice of the Bar Association, the services of Dr. C. F. McDonald, former President of the New York State Lunacy

Commission, and Dr. Arthur W. Hurd, President of the Buffalo State Hospital for the Insane. The people engaged the services of Dr. Joseph Fowler, Police Surgeon, Dr. Floyd S. Crego and Dr. James W. Putnam as experts. These five physicians examined Czolgosz at different times, separately and together, and he talked with them, giving his early history and life.

Briefly stated, Czolgosz is a young man 28 years old. Former history of good health, steady habits, not given to drink and a moderate smoker. He has been educated in the Public Schools, being in attendance at a school until he was 15 years old. He has worked in a wire works, been a blacksmith's helper and worked on a farm; altogether his life has been an industrious one. He states that his work was fully up to the average of his fellow workmen, that he never lost a day from ill health, and that his average earning capacity was from \$1.50 to \$1.75 per day. He had saved about \$400 in the last six years. He voted when he was 21 years old. At that time, having read anarchistic papers and attended meetings of anarchists, he became converted to their principles. He left the Roman Catholic Church in which he had been brought up and gave his reason for doing so, "I did not believe any longer in the things the priests told me." He said he did not believe in government, nor in law, nor in lawyers, nor in God, nor in marriage. He believed that every man should take care of himself and have no rulers. He said this was not his idea but was the idea he heard in the anarchist meetings. He said he killed the President because it was his duty. He said, "I am glad I done it." When he was offered counsel he refused it, stating he knew he was guilty, that he had no chance, and that he did not believe in law or lawyers. When arraigned in court he entered the plea of guilty, which, of course, was not allowed. During the trial he sat quietly and listened to the testimony. The case of the people was presented, being simply the testimony of eye-witnesses of the crime, the medical testimony of the surgeons who attended the President and the testimony of the post-mortem examiner. The question of the prisoner's mental condition was not touched upon by any witness. The witnesses summoned to examine the prisoner for the defence did not appear upon the witness stand, therefore the experts summoned by the people did not present any testimony. The prisoner at no time even shammed insanity. He did not, it is true, discuss the crime with his attorneys, but he did discuss it with others. His digestion and his sleep were normal. He was true to his fellow anarchists in that he refused to incriminate any of them, referring only to Emma Goldman and her lectures.

In conversation and appearance he is more intelligent than the average Polish laborer. Physically he presents the following conditions: Pulse 82; temperature 98½°; tongue, clean; skin, clear; patellar reflexes, normal; pupillary reflexes, normal; heart, normal.

THE CZOLGOSZ TRIAL: A UNIQUE EVENT.

By CHARLES K. MILLS, M. D., of Philadelphia.
Professor of Medical Jurisprudence in the University of Pennsylvania.

The trial of Czolgosz for the murder of President McKinley is a unique event in medico-legal history. The student of jurisprudence as well as the average citizen finds much to commend in the manner in which the assassin was brought to trial, a little more than two weeks after the fatal shot was fired. In less than two weeks after the death of the President he was convicted and sentenced. Great harm is done by the postponement of trials for crimes of violence, by the long drawing out of such trials, and by delays in the execution of sentence. In this case justice has moved with a celerity with which the most impatient cannot find fault.

As regards the prosecution, and especially the absence of rhetorical display and the economy of time in the presentation of the case, nothing can be said except in praise.

The only plea that could be made was that of insanity, and in order to meet this issue, if it should arise, competent physicians, including several well-known alienists, were chosen before the trial by the District Attorney and the Bar Association of the county in which the crime was committed to examine into the mental condition of Czolgosz. These physicians after separate examinations unanimously reported that he was sane, and there is no reason in anything which has appeared in connection with the case to doubt the justice of their finding. The dearth of facts, historical or special, regarding the mental condition of the murderer, is a marked feature up to the present in the published annals of the case. The crime was deliberately planned, was carried out with determination, and was said by the murderer to have been committed because of certain opinions which he held. Both previous to the trial and when he was arraigned by the court he pleaded guilty and expressed himself as prepared to receive any punishment that was meted out to him. This is about all that is known of the man and the deed, and in the light of this knowledge that justice was done no right-thinking man can doubt.

A word perhaps might be said as to the manner in which the defence of Czolgosz was conducted. This case is one of historic interest, and hereafter will pass into the literature of medical jurisprudence. Not improbably it will be referred to as a precedent in future trials.

It would seem to the unprejudiced and unimpassioned that an effort might have been made to present to the jury some evidence regarding his mental state. Instead of this his defense merely made a statement to the jury that the accused had been examined by experts and pronounced sane. This is not the usual method, and whether it is the best method will be determined not by the fact that it has met public approval, but by the verdict of time and of future events.

The address of the senior counsel for Czolgosz was of unusual character. It dealt largely with a discussion of the dignity of the law. It was in the main a defence of the defenders, who needed no defence. Only praise is to be given to those who in the face of probable misrepresentation or even of

denunciation take up a line of conduct which is enjoined upon them by duty.

In the light of the facts which are known and of the evidence presented at the trial, Czolgosz was justly convicted, and punishment should follow speedily. Not a single bit of evidence as to his insanity has been produced even in our prolific public prints, but his defence should have been as thorough as it would have been if the crime he committed had not been one which all the world execrated.

CHAS. K. MILLS.

SOME REMARKABLE FEATURES.

By WHARTON SINKLER, M. D.,

of Philadelphia.

Physician to the Orthopedic Hospital and Infirmary for Nervous Diseases.

To the Editor of the *Philadelphia Medical Journal*:

To one who has observed the course of the trial of Czolgosz for the horrible crime which he committed, several remarkable and unusual features present themselves. The contrast between this trial and that of the assassin, Guiteau, is marked, and very favorable to the method in which the District Attorney of Buffalo conducted his case. As will be remembered, Garfield was shot on July 2, 1881, and died on September 19th. Guiteau was not arraigned until November 14th of the same year. He secured counsel, who made a determined and persistent effort to save their client from the gallows. They obtained the services of at least two alienists as experts, who testified with marked vigor that the defendant was insane; they brought out his previous life and actions, and adduced much evidence to prove that he was a paranoiac. The trial lasted almost eleven weeks, and ended with the conviction of Guiteau. He was not executed until June 30th, almost a year after the assassination. Notwithstanding the amount of evidence brought forward as to the mental unsoundness of Guiteau, there never was any doubt as to the verdict which would be brought in by the jury, and the whole country heartily approved of the execution of the criminal.

In the case of Czolgosz, the defendant entered a plea of guilty. He refused to make any attempt to secure counsel, and even when two able lawyers were appointed by the Court, he apparently declined to give them any assistance in the preparation of his defence; he refused to give them any information as to his past life, or to say anything which would be in extenuation or defence of his detestable crime. His counsel seemed to have made no attempt to produce evidence as to his possible insanity, nor did they effectively cross-examine the witnesses who testified that he was sane. They merely accepted the opinion, which was secured by the prosecution, that the defendant was of sound mind and responsible for his action, and the defence which they made was merely a technical one. The trial was brought swiftly to a close in two days, when Czolgosz was sentenced to suffer the extreme penalty of the law some time during the week ending October 28th, or in less than two months from the death of his victim.

There is no doubt that the trial was conducted with the utmost dignity and impartiality, and that

the verdict was a righteous and just one. At the same time one cannot help feeling regret that the counsel for Czolgosz did not make an attempt to bring out some evidence as to the man's mental condition and his previous life. It is certain that no testimony adduced by the defence would have made any change in the verdict, and it would probably have emphasized even more positively the prisoner's entire responsibility for his act. Had the counsel for the defence gone into the question of Czolgosz's possible insanity, either by producing experts or by cross-examination of the State's witnesses, the case would have been of some interest and value to medical jurisprudence. A point greatly to be commended is, that the experts who were called by the prosecution were selected by the Bar Association, presumably in conference with the District Attorney. This method of securing experts is in the right direction, and seems the best way of proceeding in similar cases. It does away as far as possible with the personal attitude of the expert towards the side which has employed him, and from which he expects to receive his remuneration.

NOT A CASE IN PSYCHIATRY.

By F. X. DERCUM, M. D., of Philadelphia.

Professor of Nervous Diseases in Jefferson Medical College

To the Editor of the *Philadelphia Medical Journal*:

Dear Doctor:—In my opinion, the Czolgosz case presents no points for medico-legal discussion. It is difficult to comprehend how so revolting, so senseless and so useless a crime could be committed by a person of normal mental make-up—difficult to understand how a young man born and educated in this country could commit such a crime and still be mentally sound. This thought doubtless filled the minds of the counsel for the prisoner, for they caused the prisoner to be examined as to his mental condition by competent medical experts, but the fact that these experts were not placed upon the witness stand, permits of no other inference than that their examination furnished no data upon which a theory of insanity could be based. Under these circumstances the case of Czolgosz does not belong to the field of psychiatry, but to that of the psychology of crime.

On the Question of Immunity.—The mechanism of Adaption of the *Bacillus Pyocyaneus* to Sodium Salicylate.—A. Studensky (*Bolnitchnaya Gazeta Botkina*, Vol. XII, No. 9) succeeded by cultivating the bacillus pyocyaneus in bouillon containing gradually increased amounts of sodium salicylate in obtaining an organism which grew well in a medium containing 3.5% of salicylate of soda, whereas the original culture was promptly killed by 2.3% of the salt. To ascertain that no decomposition of the salt takes place he made a quantitative determination of the sodium salicylate in the culture with the result that 3.9% were found, the increase being due to the evaporation of the medium. Acting on the supposition that the organism develops a substance which neutralises the antiseptic properties of the salicylate of soda, he filtered the culture through porcelain and inoculated the filtrate with the original non-injured organism. The latter developed feebly but perceptibly. But when a portion of this filtrate was heated for 15 minutes at 90-96 deg. C. a flocculent precipitate formed and the filtrate regained its full germicidal strength. This work, which is still in progress, has been undertaken independently of the investigation of Danysz of the Pasteur Institute. [A. R.]

ON THE COORDINATION OF RESPIRATORY
MOVEMENTS.*

By DR. R. du BOIS REYMOND.

Berlin, Germany.

Privatdozent of the University of Berlin.

The nervous mechanism of the respiratory organs, though diligently studied again and again, still offers a number of unsolved problems. Taking a general view of the subject and the work done, as represented in scientific literature by innumerable papers, one may say, that out of all the problems offered, only two have mainly absorbed the attention of investigators. One of these is the origin or the primary cause of the nervous impulse corresponding to each act of breathing, the other the regulatory mechanism, by which the periodical action of the respiratory organs is controlled and adapted to varying conditions. These two questions alone form the subject of by far the greater number of all the papers on the physiology of respiration, and the universally accepted results concerning them are the basis for the observations contained in the present communication.

The origin of nervous excitation in respiratory function, if it be not assumed to be purely automatical, must be of a reflex nature. Reflexes acting on the respiratory centres being proved to exist, the hypothesis of automatical actions becomes superfluous. The reflexes in question may continually be brought under two heads: Under the first come the mainsprings of respiratory function; want of oxygen and excess of carbonic oxide in the blood. To these may be added every influence exercised on the respiratory centres by substances contained in the blood, for instance the hypothetical products of muscular excretion, which are supposed to cause the increase of respiration inherent on muscular effort, even in experiments precluding connection by nervous channels. Overheating of the blood, which acts like excess of carbonic oxide, may also be classed here. In all these cases the activity of the nervous centres is called forth by a change in the quality of the blood, therefore this class of reflex-excitations can fittingly be described by the term "stimulation by the blood." The second kind of reflex action on the respiratory centres is purely nervous, it comprises the inspiratory and expiratory effects of the vagus nerve described by Hering and Brewer, and all similar reflexes. This class is therefore to be designated as the "Stimulation by the Vagus."

These two classes of reflexes being held to supply the periodical excitation required for the normal innervation of respiration, the question as to the origin of the respiratory stimuli may be considered as satisfactorily answered. Next to this question the problem of regulation of the rhythm has mainly been studied. Considering the whole respiratory apparatus as a unit, such as could be excited to movement in its whole extent by any single stimu-

lus, this stimulus given, the regulation of rhythm would in fact be the next important point in the function of respiration. But far from being such a unit, respiratory mechanism on the contrary is a specimen of complex coordinated machinery. Respiratory movement is brought about by a considerable number of different muscles distributed in regions widely apart and acting together in separate more or less clearly defined groups. Thus the intercostals, several accessory thorax muscles, the diaphragm, the muscles of the larynx and palate, the muscles of the alae nasi, act together to produce a normal act of breathing. To these, according to Sandmann, ought to be added the unstriped muscles of the bronchi. In the face of so complicated an arrangement the next question to consider evidently should be not the regulation of rhythm, but the coordination of movement. It seems that this question, though it has to a certain degree occupied physiologists, has not hitherto received the attention due to its importance.

The coordination of respiratory movement, like every other coordination must be due to coordinate action of the groups of motor cells corresponding to the different muscles. This coordination can be explained in two ways. The one is, that each of the motor cell groups responds to the occurring stimuli independently and without any relation to the action of the other groups, but that the excitability in each separate group is prearranged in such a manner as to produce that ratio of responses, the totaleffect of which we call a coordinated movement. This explanation postulates so complicated and delicate modifications of excitability, that it can hardly be seriously advanced. It is mentioned here merely to complete the series of possible suppositions. The other explanation is, that in the same way as the separate motor cells of each group are combined in the groups corresponding to the separate muscles or parts of muscles, these groups in their turn combine to groups of a higher order, corresponding each to a whole group of muscles, and that these groups are again subordinate to groups of a still higher order, so that at last the whole number of motor cells is controlled by one single group, representing a unity in the sense above mentioned, a true motor centre, a "*noeud vital*". Although this view of the matter has been objected to, it is so well borne up by the analogy of other coordinated movements, and, moreover, appears at first sight so simple and natural, that it may be said to have been generally adopted. But it is only on superficial examination that this explanation seems so easy and simple. On second thought it will be seen, that automatism, after having been done away with in the matter of primary stimulus, crops out afresh in the shape of a wonderful faculty with which the nervous centre would have to be endowed, viz., the faculty to supply each of the subordinate cell groups with exactly the required amount of nervous impulse at exactly the required time, so as to respond by a coordinated movement to a single stimulus. There is not much difference between a centre which acts automatically and one that on reflex excitation distributes at times of its own accord a number of

* A further account of the matter will be published in "Engelmann's Archiv für Physiologie."

different mechanisms so as to make them work for a common object in most perfect coordination. Compared with these difficulties even the hypothesis of separate centres with adjusted excitability mentioned before appears improbable no longer. But both theories fail when stress is laid on the power of the nervous mechanism to adapt itself to all kinds of complicated needs, such as for instance one sided breathing in cases of disease or accidental or experimental lesion. And both theories, as they have hitherto stood, fail likewise to explain an observation to which attention is to be called by the present paper, and which will be shown to open up a new line in the study of coordination of respiratory movements.

In the course of certain experiments on excitation of the larynx from the medulla,* it was noticed, that when the animal ceased to breathe, either from overdoses of ether, or from injuries to the medulla, and artificial respiration by manual compression of the thorax was resorted to, the glottis showed regular accessory movements synchronous with the artificial respiration. These movements were not due to the direct mechanical influence of the manipulation, for they were absent in dead animals. Neither were they caused mechanically or by reflex, by the passage of the air through the glottis, for they occurred without alteration when a canula was placed in the trachea so that the air could not pass through the larynx. Moreover, as was known beforehand, when a canula was introduced in an upward direction and air artificially blown or sucked through the glottis, no reflex action of the kind was found to take place. These direct influences being excluded, the movements observed would appear to be produced by excitation of central motor cells, and probably by the same groups of cells that generally perform the normal respiratory function. Thus this observation would be a proof of the excitation of one separate respiratory centre. Now there are, as shown above, only two classes of reflexes known to affect the respiratory centres. It ought then, to be either "excitation by the blood" or "excitation by the vagus" that produces the movements in question. As regards the first supposition, it would be quite possible that the artificial respiration, supplying the circulation with air, was in each of its phases accompanied by a change of the quality of the blood sufficient to evoke a response of the larynx motor cells. Now "excitation by the blood" can readily be excluded from the conditions of the experiment, by producing apnea in the animal. If there is so great an excess of oxygen and so small an amount of carbonic oxide present in the blood, that the respiratory movements of the thorax and diaphragm cease, we may be sure, that the blood stimuli are also abolished in relation to the larynx. On trying, therefore, the experiment on an animal previously brought into a state of profound apnea, rhythmical pressure on the thorax as in artificial respiration was found to be accompanied by accessory respiratory movements of the glottis as before. On the lines drawn above

the only supposition left is then, that excitation of the larynx motor cells occurs by the vagus. The rhythmical compression and relaxation of the thorax of course compresses and dilates the lungs, so it is again quite possible, that the sensitive fibers of the vagus in the lungs are by the artificial respiration excited sufficiently to wake a response of the larynx motor cells. Now again, this excitation by the vagus can be readily excluded from the conditions of the experiment. If, during apnea, the thorax be opened, so that the lungs collapse and remain unaffected by passive movements of the thorax, surely rhythmical excitation by the vagus can be assumed no longer. On repeating the experiment under these conditions, every compression of the thorax was still found to be accompanied by respiratory movements of the glottis. Moreover it could be clearly shown that to each compression of the thorax corresponds an adductive, or closing (expiratory), to each relaxation an abductive, or opening (inspiratory) movement of the glottis.

All known sources of excitation of the respiratory centres having been excluded by the conditions of the experiment, viz., complete apnea and complete pneumothorax (or in several cases section of the vagus below the origin of the recurrent nerve), the phenomenon must be due to a hitherto unknown kind of reflex. In this new reflex the passive movements of the thorax act as a stimulus which gives rise to an afferent impulse exciting the motor centre of the larynx. For sensory organs originating this impulse we must evidently look to the sensory organs of the thorax articulations, tendons and muscles. The afferent channel must evidently follow the path of the intercostal nerves and reach the reflex centre by way of the spinal cord. Section of the spinal cord below the medulla arrests the respiratory movements of the larynx even though artificial respiration be continued. Thus it appears that the respiratory movements of the larynx are dependent at least in part upon the excitation of the muscular sense or posture-perceptive sense of the thorax. The coordination of respiration is in this case shown to be exactly analogous to the coordination of different muscles in the motion of the limbs. Very likely the other separate parts of the respiratory mechanism are linked together by similar reflexes. Experiments on the coordination of the diaphragm and the larynx have already shown, that in this case there exists a connection by means of the vagus excitation. Peripheral stimulation of the severed phrenic nerve calls forth movements of the glottis, which cease after section of the vagus below the recurrent nerve. Continued research will probably bring to light additional data of the same kind.

By these results the difficulty of explaining the coordination and adaptation of the respiratory movements is considerably diminished, especially because "excitation by posture perception" presents itself as an agency extremely well adapted to bring about the exact adjustment of nervous discharge required for proper coordination.

The experiments referred to moreover explain in a very satisfactory way the reviving influence of artificial respiration on the respiratory centres. Hitherto this would have been considered wholly due to

*These experiments and those hereafter described were executed in the Physiological Laboratory of the *Thierärztliche Hochschule* of Berlin, in collaboration with the *Laryngologist*, Dr. T. Vratzke, of Berlin.

the supply of oxygen and diminution of carbonic oxide in the blood inherent on ventilation of the lungs, but the above experiments prove that artificial respiration at the same time acts as a direct stimulus at least on the larynx motor centre, and probably on other respiratory centres as well. In this connection it may be of interest to note the negative fact, that rhythmical drawing out of the tongue, in the cat and the dog was quite without effect on the movement of the larynx, even in such cases in which spontaneous accessory movements of the tongue in active respiration were well marked.

A CASE OF TRANSPLANTATION OF THE URETER FOR THE CURE OF URETERO-VAGINAL FISTULA*

By A. LAPTIIORN SMITH, M. D., M. R. C. S., (Eng.),
Of Montreal.

Fellow of the American and British Gynecological Societies and of the London Obstetrical Society; Professor of Clinical Gynecology in Bishop's University, Montreal, and Professor of Surgical Diseases of Women in the University of Vermont, Burlington; Surgeon in Chief of the Samaritan Hospital for Women; Gynecologist to the Montreal Dispensary and to its Western General Hospital, and Consulting Gynecologist to the Women's Hospital, Montreal.

History. Mrs. J. B., 34 years of age, married, came to me at the Montreal Dispensary on the 1st of July, 1901, giving the following history. She began to menstruate at 14, was always regular and flow was painless. She was married at 31, and had one child at 32 while living in Vancouver, B. C., the labor being very difficult and requiring the use of forceps. So much force was employed that the vagina was terribly lacerated, and ever since then, two years and seven months ago, there has been a constant flow of urine by the vagina which burned and excoriated it and the vulva, so much that she has been in constant pain, as well as misery from being always wet, and in spite of scrupulous cleanliness, always smelling of urine. About 18 months ago patient went to London, Eng., to be treated, and entered St. Bartholomew's Hospital, where she remained for three months, and where a thorough examination of the urine was made and the quantity coming from each ureter and from the bladder and fistula respectively, was measured carefully. While there she was anesthetized three times, once to make a diagnosis, and twice for vaginal plastic operations with a view to close up the fistula, neither of which, was, however, successful. These plastic operations explain why the vagina had assumed such a conical shape, and why the tissues were so brittle that my stitches would not hold in them. The English surgeons, she said, had spoken of ureteral transplantation, but she was so exhausted and discouraged that she would not remain in the hospital any longer than three months. She came back to Canada a year ago and continued to suffer until she was advised to come to the Montreal Dispensary. On attempting to examine her there, it was found impossible to do so without an anesthetic, owing to the extreme sensitiveness of both vulva and vagina, both of which were covered with excoriations and ulcers. Steps were at once taken to render the urine less irritating and as soon as a bed was vacant she was admitted to the Western General Hospital. With regard to her family history there was nothing of interest, except that her mother died from difficult childbirth, showing that a small pelvis is inherited.

Diagnosis. Before deciding upon any operation it was essential to make an accurate diagnosis. The urine was running away from the vagina; but where was it coming from? The bladder or ureter? And if the latter, which ureter? As the patient was extremely sensitive she was anesthetized, and the bladder having been emptied with a catheter, it was then filled with sterilized milk, while the vaginal vault was carefully dried; only a small part of a drop of milk was seen to come from the apex of the

funnell forming the vaginal vault on the patient's right. An effort was then made to pass a probe into this tiny opening and thence into the bladder, but at first this could not be done. Finally, however, the probe passed into the right ureter, a distance of six centimeters. While the probe was in the ureter a ureteral sound was passed into the bladder and seemed to enter a short distance into the ureter because a little jet of urine came from it, while the bladder had methyl blue solution in it. But it was impossible to make the two metallic instruments touch each other, although a great deal of trouble was taken to do so, thus showing there was a stricture of the ureter below the fistulous opening into it. This also proved that it was really a uretero-vaginal and not merely a vesico-vaginal fistula. As the quantity of urine coming from the fistula was less than the total quantity secreted by the kidney on that side I came to the conclusion that there was some obstruction to the flow into the bladder as well as difficulty in the escape of the urine from the fistula; in other words: 1st, that there was no vesico-ureteral fistula, 2d that part of the urine passed by the natural valvular opening into the bladder, which valve prevented milk or methyl blue solution from passing from the bladder into the ureter; and 3d that the fistula was not merely a vesico-vaginal one. The quantity passing by the fistula was ascertained in the following manner: The catheter was passed into the bladder every two hours and the quantity measured. Then the patient was made to sit on a chamber for two hours on several occasions and the quantity which dribbled away was carefully ascertained. While the two quantities together measured sixteen drams every two hours the quantity which dribbled away in that time was only five drams, while the quantity drawn from the bladder was about eleven drams. After the examination the fistula closed up completely, and for five days she was perfectly dry for the first time in eighteen months. The explanation of this temporary improvement was that the manipulation with the probe had set up a local inflammation with swelling of the lining of the fistula so that its calibre was closed. In a few days, however, the wetting of the bed clothes began again, and I decided to operate for its closure. Being loath to resort to the serious operation of transplantation of the ureter until I had first given her the chances, however small, of having it cured by a vaginal plastic operation, the latter was undertaken with the promise to the patient that if it failed, as it had done twice in London, I would almost surely cure her by opening the abdomen and transplanting the ureter. Bovee, in his excellent paper, says: In but few of the uretero-vaginal fistulae can cure be procured by vaginal plastic surgery. The danger of relapse from heavy strain, from cicatricial contraction, is too great to permit this plan to be adopted in any but the most favorable cases.

Vaginal Operation. The fistulous tract was dissected with sharp curved scissors and tenaculum and three silk-worm gut sutures were passed around it with great difficulty, owing to the mass of cicatricial tissue in the vagina reducing this canal very much in size and making it conical with the point of the cone exactly at the fistula. Much to my regret this only stopped the flow for a few days after which it was worse than ever. One more attempt was made, this time by removing a strip of vagina all around a distance of one centimeter and then bringing the raw surfaces together. This was exceedingly difficult but was finally accomplished. But the tissues were so friable that the stitches cut through and the patient was still worse. The poor woman was by this time very much discouraged, and worn out physically, so that I felt fully justified in doing the more radical operation, and at the same time was more sure of effecting a cure, and to this the patient readily consented.

Transplantation of Ureter. On the 17th of August, 1901, assisted by Dr. England, and Dr. Gillespie, the following operation was undertaken. The abdomen was incised in the middle line from the pubes to the umbilicus down to but not through the peritoneum. The latter was then easily pushed off the abdominal wall on the right side and not only the bladder but also the large vessels of the pelvis were exposed to view, my intention being to find the ureter and to cut it off close to the fistula and to transplant it into the bladder higher up, without opening the peritoneal cavity at all. Although I nearly succeeded in doing so, and would have no difficulty in doing so should I ever have a similar case, yet

*Read at the Meeting of the Canada Medical Association at Winnipeg, Aug., 1901, and published synchronously with The Dominion Medical Monthly.

on this occasion several circumstances threw me off the track and I was eventually obliged to follow the same plan as I had seen Sanger follow in a similar case in Leipzig when I was there three years ago, namely to open the peritoneum running over the large vessels at the brim of the pelvis and to feel for the artery, see the vein and pick up the third tube which was the ureter. One of the circumstances above referred to was the vomiting which started violently the moment the anesthetiser ceased to pour on the anesthetic, and this he stopped doing because she was so weak; and another was the distention of the stomach and colon with gas, although the bowels had been well moved and the small intestines were collapsed. The third circumstance was the retroversion of the uterus, owing to which I found two round tubes dipping down into the pelvis, one being the ovarian vein, and the other the round ligament. I mention these little difficulties so as to help any of my hearers who may have to perform this operation. Had it not been for the vomiting and the distention of the large bowel, the intestines would have been easily pushed into the upper abdomen as the patient was in the highest Trendelenburg posture, without which, indeed the operation for me would have been well nigh impossible. Another cause of the difficulty in finding the ureter was in not first passing the probe into it from the vagina before the operation, for when I asked one of my assistants to do this during the operation he was unable to find it. When at last I was reluctantly compelled to open the peritoneal cavity I had only to make a little slit in the peritoneum lining the wall of the pelvis, in the line of where I knew the ureter should be, when I quickly came upon it and picked it up. About one inch of the lower end of it was imbedded in cicatricial tissue and of course this much of it had to be sacrificed; a silk ligature was passed around it while my assistant pulled it taut and tightly tied and cut it off. The ureter was then severed a little above the ligature and covered with a gauze sponge as urine at once came from it. As most of the deaths or failures to unite have been due to the septic condition of the urine I had taken the precaution to administer urotropine for a week before so that I was not afraid of a drop or two escaping; and as stricture of the ureter is another cause of failure I did not wish to bruise it with a forceps. We all thought it much thicker than we had ever seen it before, perhaps the obstruction at the site of the injury had caused it to hypertrophy as it is a muscular tube capable of peristalsis. The end of the ureter was split open to a distance of a third of an inch so as to avoid subsequent strictures after it was transplanted, an accident which has marred the success of more than one case where this was not done. A slit was then made obliquely into the right upper corner of the bladder and the ureter stitched into it, the mucous membrane of the ureter to the mucous membrane of the bladder with very fine chromicised catgut, and the fibrous coat of the ureter to the muscular wall of the bladder with six fine black silk stitches. In doing this Van Hook's method was employed, which will be described later on. The bladder was then distended with a pint of weak methyl blue solution and to my delight not a drop leaked through the point of transplantation. The two inch cut in the peritoneum was closed with fine catgut, as was also the opening in the parietal peritoneum. In case that the transplanted ureter should fail to adhere, a drainage tube was passed down from the end of the incision in the abdomen to a little below the opening in the bladder, and a piece of iodoform gauze down to the lowest point between the peritoneum and the pelvic fascia. The abdomen was closed with silk worm gut and the patient went off the table in fair condition. Apart from the vomiting which lasted three days, she has made an excellent recovery. The catheter-a-demeure was left in for five days, by which time I believed that the ureter was firmly attached in its new place. It is now ten or eleven days since the operation and the patient can hold her water for eight hours and is rapidly regaining her health and strength.

Remarks.—This case is of interest for several reasons: First—It is as far as I am aware the first time that the operation has been done in Canada and my Canadian brethren will, I am sure, share my pleasure in seeing it result successfully. It had been done successfully ten times in Europe and the

United States up to May, 1899, including the one I saw Sanger do in Leipzig. The first successful experiments on animals were performed by Paoli and Busachi in 1888. The end of the ureter was split before suturing it into the bladder.

Novaro (*Centralblatt f. Chirurg.*, 1893, vol. XXVII, p. 596), following their method, performed the first operation on man. He made an incision in the end of the ureter 1 cm. in length. Although there was some leakage for a few days there was a successful result. Penrose (*University Med. Mag.*, April, 1894), Krug (*Journal Obstetrics and Gynecology*, N. Y., 1894, p. 469), and Baldy (*Amer. Journal Obstetrics*, 1896, Vol. XXXIII, p. 362), performed similar operations, employing the idea suggested by Van Hook in his anastomosis operations, namely, introducing two traction sutures each with a needle at both ends, which is passed through the wall of the ureter from within out, forming a loop on its inner side. Both sides are now carried through the bladder wall from within out coming out on one side of the incision. A similar suture is placed on the other side and the ureter drawn into the bladder opening by traction on the stitch and fixed there by tying. The only difference in my case was that I did not pass three silk stitches through the bladder mucosa, which I think a weak point in Van Hook's otherwise excellent method. In Baldy's case the proximal end of the ureter was too short to go to the bladder without too much tension on the sutures, so he brought the bladder over to that side of the pelvis by two stout catgut sutures. Kelly (*Johns Hopkins Bulletin*, Feb., 1895) gained one inch in his case by dissecting the bladder from the horizontal rami of the pubis and dropping it back into the pelvis.

Boldt (*Amer. Journal Obstetrics*, 1896, Vol. XXXIII, p. 844) passed a ureteral catheter into the fistula before the operation, which I forgot to do until after I had begun, and thus found the ureter more easily; after cutting the ureter off he left the catheter in the proximal end and passed it into the bladder through the opening and out through the urethra, thus running less risk of leakage if his union had failed.

Fullerton (*Kelly's Operative Gynecology*, Vol. 1, p. 463) severed a double ureter on right side. As soon as detected she closed the distal end and introduced both proximal ends into the same opening in the bladder, with good result.

Baum, Witzel, Vert and Kelly have performed extraperitoneal implantation into the bladder and although they were all obliged, as I was, to open the peritoneum for a few minutes to find the ureter, I believe that with a little more experience we could complete the operation extraperitoneally, thereby reducing the small death rate, Kelly having lost but one case on the seventh day from sepsis.

Second—My case is interesting, because the injury to the ureter was caused by delivery of a child. In the majority of cases it has resulted from difficult operations, mostly vaginal hysterectomies.

Fergman found that in sixty-five cases of ureteral fistula, twenty-five were due to parturition, in sixteen of which the forceps were employed. In twelve, vaginal hysterectomy was the cause; two

by stone in the ureter, and ulceration; three by abdominal section; one had a traumatic origin; two from pelvic abscess; one from a pessary; one from tubercular necrosis of the ureter as in Krame's case.

Third—It shows the value of urotropine in making the urine aseptic; my patient had a temperature of 103° a week before the operation, which may have been due to infection of the ureter, but if this was so, the urotropine apparently remedied it, for there was no temperature whatever after the operation.

• Fourth—Owing to the extensive bruising at the time of the confinement and also owing to the four plastic operations, the vagina was reduced to a very small cone of cicatricial tissue, so that repair by this means was out of the question. In a large and capacious vagina I believe that the ureter could be found and repaired by splitting open the vagina and exposing the base of the bladder as in my method of repairing severe vesico-vaginal fistulae. In no case should we implant the ureter into the bowel nor tie the ureter so as to cause hydronephrosis. Nephrectomy even as a last resort is hardly justifiable in view of the possibility of there being only one kidney and of the splendid results of transplantation of the ureter.

SOME OF THE OCULAR AFFECTIONS OF CHILDHOOD ASSOCIATED WITH IMPAIRMENT OF GENERAL NUTRITION.*

By S. D. RISLEY, M. D.,

of Philadelphia

Attending Surgeon to Wills' Eye Hospital, Philadelphia.

It is not my design in this paper to treat of the more frequently occurring forms of ocular inflammation, as for example, blepharitis ciliaris, styes, phlyctenular conjunctivitis, ulcers of the cornea and affections of the lachrymal apparatus, etc., etc., occurring in strumous or rickety children. These forms of disease are very frequent and too well known to make their discussion before this society either interesting or valuable.

There is, however, a group of ocular affections, fortunately not so frequent, which like the group already mentioned, are certainly associated with, and probably in a large measure dependent upon malnutrition. While in the forms of disease already enumerated the manifestations are so pronounced that they cannot be overlooked and are therefore not likely to be neglected, in those to be studied, neither the local affection nor the general impairment of health are necessarily so obvious as to drive the parents to seek professional advice.

Moreover, the very striking forms of disease already mentioned and characterized by great photophobia and lachrymation, by phlyctenular ulcers of the cornea and bulbar conjunctiva; by impaired alimentation and bowel disturbance usually occur in early childhood; whereas the conditions I wish to describe come on later and are essentially a disease of adolescence, although probably not necessarily dependent upon the peculiar conditions of vitality which often obtain at that time of life, but are rather to be regarded as a part of the general ensemble of symptoms which, in the female, are

associated with a faulty establishment of the menstrual function, and in both boy and girl with irritability of temper and a wide group of ill-defined nervous symptoms. These more or less vague and subtle symptoms of disease are frequently ascribed to errors of discipline, to rebellion upon the part of the child against parental authority, in a word, to bad temper, a mistake which often leads, both at home and in the schoolroom, to some form of punishment, when instead the advice of a physician should be sought. The history of two cases will suffice as illustrations of these remarks and incidentally as pictures of the conditions I have met in a large number of children. It may be asked that since the ocular symptoms are but a part of the general malady, why present these cases from the standpoint of the ophthalmologist? For two reasons: In the first place, the general conditions had not been recognized. In the second place, the ophthalmoscopic study of the fundus oculi, the character of the field of vision, etc., were the means by which attention was first called to the serious impairment of the general health.

CASE 1.—S., aged 10, was brought to me in 1897 suffering with headache, inability to read characters on the black-board at school, blurring page, dread of strong light and attacks of red eyes. No complaints were made by the parents or his physician of any general derangement of health, indeed, in appearance the child was a model of the sturdy, healthy school boy. A careful study of the ocular conditions revealed only the presence of a high degree of hypermetropic astigmatism and the attending congestion of the fundus oculi from accommodative strain. The refraction error was corrected by glasses and the symptoms promptly disappeared. Two years later, now at twelve years of age, the boy was brought to the office again with a return of the severe headache and petit chorea. The pains were paroxysmal, were often induced by near work with the eyes, by exposure to sunlight and were aggravated, indeed often produced by the noise and contention of his brothers and sisters at home. During the consultation his mother sent him from the room and then related that the boy was completely changed in disposition. Instead of the reasonable, cheerful, affectionate and obedient child he had always been, he was now subject to moroseness, to sudden fits of the most ungovernable temper, during which he would strike his mother with any weapon at hand, would, if not restrained, do violence to his younger brothers and sisters. So serious had the matter become that he was a terror to the household, and his mother did not dare to leave home without taking him with her. He had lost interest in his school work, where he was regarded with aversion by both teacher and children. A painstaking study of the eyes revealed a change from far sighted to near sighted astigmatism, accounted for only by stretching of the eyeballs. The ophthalmoscope revealed a notable change in the fundus. The veins of the retina were full and dark, and there were faint greyish lines along the borders of both arteries and veins. The optic discs were too capillary, the borders of the nerve partially concealed by the hazy retinal fibers, while the entire eyeground was a cinnabar red, flummy in appearance, and there were granular changes in the macular region of both eyes, and between the macula and nerve. Elsewhere in the fundus there were beginning absorption areas. The breath was offensive, he had developed hypertrophied tonsils and a boggy condition of the tissues over the inferior turbinates. The urine was high colored, highly acid in reaction and had a sp.gr. of 10.28; no sugar was detected at any time, but there was intermittent albuminuria and frequent deposits of red crystals after standing. The changed refraction conditions were once more carefully corrected under atropia, and the boy was then returned to the family physician with the suggestion that he be taken from school, the opinion being given that while his headache might be due in part to the ocular conditions which have been described, the local pathological state was probably intimately

* Read before the Pennsylvania State Medical Society, Sept. 1901.

associated with the general impairment of health and faulty metabolism. His diet was carefully regulated, he was sent to the seashore, where he spent his days in the open air, his eyes being protected with smoked glasses. The bowels were kept free. Iodide of iron and arsenic alternating with syrup of hydriodic acid and bichlorid of mercury were administered internally. Improvement in all conditions rapidly followed, so that in three months the boy returned to school quite his former self. The conditions of the fundus oculi disappeared gradually, leaving only the absorption scars. It is probable that had it been possible to study the mesodermic tissues elsewhere than in the eye-ground under equally favoring conditions, corresponding pathological states would have been discovered. Several months previously this boy had had an attack of scarlatina followed by whooping cough, and later conditions which seem to have been obscure, but were called meningitis by the attending physician. Special attention is directed to the change of refraction in the eyes, which was of such a nature as to be explained only by the actual distention or enlargement of the eyeballs.

CASE 2—M. E., aged 11. A thin girl, tall for her age, was brought to me for weak eyes and headache. The lips were bright red and thick, the lower one falling in a listless way from the upper. The complexion was sallow, she had acne of the forehead. The hair was abundant, straight, dry, and yellowish white. Her movements were listless, she was apathetic in manner. When asked to sit down she sunk sideways into the chair, her hands fell into her lap for support, the shoulders fell forward and she sat a picture of listless apathy. The nostrils were stuffed by boggy turbinates, and to avoid labored breathing through the nose, she kept the mouth partly open. The blue eyes were partly concealed by long, almost white eyelashes and heavy drooping lids. They were unduly sensitive to strong light; the caruncles were swollen and both bulbar and tarsal conjunctiva were injected and the retrolarsal folds were thickened. Vision was reduced to 6/XII. She did not get on well at school and always returned with headache and increased redness of the eyes. She was irritable with her brothers and sisters, bad tempered and subject to alternating moods of exhilaration and depression. Her sleep was disturbed, her appetite precarious. The ophthalmoscope revealed hypermetropic astigmatism in low degree, but both optic nerves were swollen, the margins being obscured. The arteries were probably of normal size, but were inclosed in grey borders. The veins were large and dark. The entire fundus was fluffy, showing areas of pigment absorption in many places, especially marked between the nerve and macula, and in the right eye granular changes in the macula and faint yellowish spots surrounding it. The field of vision for form was concentrically contracted and about equally so in both eyes, the color fields were reversed as in hysteria, the urine had a high sp.gr. with abundance of urates and at times small quantities of albumen at repeated examinations on several successive days. She was under a colleague's care for the nasopharyngeal conditions.

She was taken from school, sent to the country, her diet and general regimen carefully supervised and tonics and alteratives administered. The general conditions slowly improved, the hysterical reversal of the color fields disappeared and the field for form increased, but at no time became normal. This child has been under observation and treatment to the present time, subject to frequent sudden relapses, followed by slow improvement. At twelve years of age, faulty, painful and irregular menstruation supervened, leading to more or less acute exacerbations of the ocular conditions at each period. The hypermetropic astigmatism has given place to myopic astigmatism. The local conditions are of interest because of their obvious association with faulty metabolism.

Remarks:—It will be observed that each of the related cases are characterized by the same group of interesting and important conditions. First—There was present in each impaired general vitality associated with many evidences of faulty metabolism. These conditions were manifested not only by the abnormalities in the urine, but by a group of interesting general and ocular symptoms. Headache, general malaise, precarious appetite, variable

temper. Second—Accompanying these general symptoms was the asthenopia, that is to say, fronto-occipital headache, undue sensitiveness to light, inability to use the eyes with comfort, impaired acuity of vision, injected lid borders and conjunctiva, chronic irritative changes in the fundus oculi passing into pathological change in the retina and choroid, causing impaired nutrition of the globe and a distention of its coats as shown by the increasing refraction. It is of importance to note, however, that in both cases there was at the beginning congenital hypermetropic astigmatism. It is of interest, therefore, to inquire whether, in the absence of this congenital anomaly of vision, and given the existing faulty metabolism, the pathological ocular conditions would have occurred. My own belief is that they would not. On the other hand, I believe that, given the congenital abnormalities in the eyes, the pathological states which caused the distention of the balls, would have been less liable to occur in the absence of the impaired metabolism. Another inquiry, however, must present itself to the ophthalmic surgeon, viz., as to what extent the eye strain at school, with its accompanying headache and other reflex nervous symptoms, may have influenced the general health of these patients. I need not in this presence stop to speak of the potent influence of reflex disturbance over nutrition. It may not be amiss, however, to bring to your attention the unfortunate situation of a growing child subject to the confinement of the school room and the many trials and anxieties incident to school life, when we add to these untoward influences the suffering from hot and painful eyes and fronto-occipital headache consequent upon the eyestrain in overcoming some ocular anomaly. The symptoms more or less constantly present are aggravated by every attempt at reading. Such a child, after attempting in the evening family circle to prepare the lessons for the morrow, will go to bed, fagged, with burning eyes and tired aching head, and is necessarily consigned to a restless, dreamful night, instead of the repose so natural to healthy childhood. That these local conditions, together with the circumstantial environments of its school and home life may lead to impairment of the general health needs no demonstration.

Congenital Smallpox.—Henri Roger reports 11 infants, born while their mothers had smallpox, all of whom had true smallpox at birth. One infant was born the day after his mother contracted the disease. In six cases, labor occurred before the eruption appeared upon the mothers. At birth these children looked healthy, and smallpox was only suspected. But the temperature was subnormal constantly. Three of these infants died before any symptoms of smallpox had appeared, having shown low temperature and jaundice only. In another case erythema appeared just before death. In three cases the eruption became pustular as in adults. At the autopsies, degeneration of the liver and kidneys, with hemorrhages, was found in all cases. One case only recovered, whose mother had been vaccinated when seven months pregnant. Death occurs in the low temperature stage, or the eruption appears with fever, and death occurs later. The eruption generally is papular and discrete, and but few pustules are ever seen. Syncope is the cause of death usually. (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, 1901, No. 12). [M. O.]

ADDRESS IN OBSTETRICS.*

By DAVID S. FUNK, M. D.,
of Harrisburg, Pa.

Mr. President and members of the Medical Society of Pennsylvania.

There can be no question that the dawn of the new century finds the expectant mother surrounded with much less of real peril than ever before in the history of medicine. The almost total banishment of puerperal sepsis from the maternity ward and the lying-in chamber; a more perfect knowledge of the anatomical relations existing between mother and child; increased manipulative skill in the management of mal-positions and mal-presentations with reference to these relations; a further perfection of mechanical appliances and a complete mastery in their use; the immediate repair of injury to the soft parts; a keen appreciation of the conditions underlying the state of pregnancy from its inception to its completion; the recognized value of prompt surgical interference in complications hitherto deemed unsurgical in their character; a clearer conception on the part of the profession at large as to what constitutes meddlesome midwifery; have each and all been instrumental in placing the science and art of obstetrics fully abreast with the most advanced thought in other departments of medicine. If other evidence were wanting than that afforded by recent standard authorities on this subject, a glance at the work done and the character of the contributions which have appeared in our representative medical journals at regular intervals throughout the year should be sufficiently convincing. Scarcely a subject but has been dwelt upon with more or less elaboration and detail. From the vomiting of pregnancy and the puerperal state to cesarean section and symphyseotomy, many of these articles bespeak most careful observation and patient and conscientious work in their preparation. At this time, however, it shall be the purpose of the writer to present very briefly the present status of several of the more serious obstetrical complications and operative procedures.

Placenta Previa.—From the standpoint of the general practitioner it is more than likely that placenta previa, with its maternal mortality of 25 to 40 per cent. and its fetal mortality of 50 to 80 per cent., will continue to remain for some time to come one of the most disquieting and alarming of obstetrical complications; and this for two reasons: First, because there can be no prophylaxis; second, because of the appalling rapidity with which it frequently destroys life. That it is not a frequent complication is evidenced by the fact that there was not a single case of placenta previa in the first 1,600 cases in the New York Emergency Hospital. It must be conceded, however, that the actual occurrence of this complication is somewhat more frequent than this record would indicate, and from statistics at hand it would appear that one case in every 800 or 1,000 cases would be more nearly correct. In keeping with these statistics the writer may be pardoned a personal allusion when he says,

that in an experience of over twenty years as a general practitioner, he has yet to meet with his first case of placenta previa in his own practice. The inference is, therefore, that it is not possible for the average general practitioner, aside from hospital practice, to develop any special skill in the management of these cases, from the element of experience. This can scarcely be said of any other complication in labor. It becomes at once apparent, therefore, how it happens that the personal equation of the attendant assumes so important a roll in the ultimate outcome of these cases. Lusk evidently had this thought in mind, when he said that "a self-poised, cool, resolute man, with clear ideas of anatomical conditions to be dealt with, would, if summoned in time, deprive even placenta previa of much of its terrors." While it is undoubtedly true that the management of placenta previa in the hands of experts has shown a steadily decreasing maternal mortality, it must be admitted that not much real progress has been made in the last three hundred years; for then as now the conditions attending it were clearly recognized, and the treatment in vogue, the early emptying of the uterus. As to when and how this shall be done are still debatable questions. Debatable for the reason that, even in the best surroundings and in the most skilful hands, the results, when the lives of both mother and child are taken into account, are not entirely satisfactory. In the hands of the general practitioner they must of necessity be far less so. Under these circumstances the maternal mortality becomes much greater under any of the former classical methods of procedure; the infant mortality being as high as 80 per cent. As to the time for emptying the uterus, it is insisted upon that it shall be done just as soon as the diagnosis shall have been made. This does not, of course, contemplate any consideration for the life of the child. It is this fact especially which has prompted observers, in this field to elaborate some method of procedure which would be attended with less risk to the child without further endangering the life of the mother. The popular method, both in this country and in England, viz., manual dilatation with version, it is claimed does not always meet this indication, and in its stead cesarean section is proposed as an operation of election, in cases, first, of complete previa; second, cases of previa in primipara when signs of fetal or maternal exhaustion are evident; third, when the condition of rigid os is present; fourth, when there is a history of previous operative delivery; fifth, in transverse positions and cases of prolapsed cord, when the cord is not easily returned.

The objections most recently urged against manual dilatation with version, exclusive of the high infant mortality, are, first, that it is frequently very difficult to do and does not arrest hemorrhage; second, the fetus is always shocked from loss of blood from the placenta and from manipulation of the cord; third, the aftercoming head must frequently be perforated.

Symphyseotomy.—Symphyseotomy, as an operation of election, while still very popular in France with a few operators, would appear to be gradually displaced by Cesarean section in this country in

* Read at the meeting of the Pennsylvania State Medical Society, Philadelphia, Sept. 1901.

those cases in which the disproportion between the child and pelvic outlet is of such character as to render a high forceps operation impossible or dangerous.

The ground is taken that the mortality of Cesarean section is less than 5 per cent. in uninfected cases and in the hands of competent operators, while the most enthusiastic advocates of symphyseotomy show a corrected mortality of six and seven-tenths per cent. In addition to this the advocates of cesarean section call attention to the comparatively brief convalescence after this measure as compared with symphyseotomy. Patients can walk after three weeks in cases of cesarean section, whereas in symphyseotomy four times as long a period is required. Fetal mortality in Cesarean section is almost nil, while in symphyseotomy it is anywhere from 9.5 to 13 per cent. Furthermore, it is urged that it is frequently impossible to determine sufficiently accurately the size of the fetal head and that even after doing a symphyseotomy it occasionally becomes necessary to do an embryotomy before delivery can be effected. The great danger to the urethra is also emphasized when there is too great a separation of the symphysis. Those who favor symphyseotomy in this country would seem to argue along two lines only: First, the operation can be performed when the condition of the patient would preclude the possibility of a more radical operation; second, symphyseotomy can be successfully done at the patient's own home and by her own attendant, the only instruments required being an obstetrical forceps and an ordinary tenotomy knife. A directly opposite view is taken by those who favor Cesarean section. These insist that neither of these operations should be attempted by anyone, who has not had considerable experience in major surgical procedures.

The weight of evidence would appear to be in favor of Cesarean section as an operation of election, and that before any prolonged attempt has been made to deliver with instruments, with the possible result of serious injury to both mother and child; but when this has occurred and there exists the possibility of infection, symphyseotomy would seem to afford the better prognosis. In the matter of the performance of the operation of symphyseotomy, the subcutaneous method is preferred, the symphysis to be brought firmly together and held in apposition by silver wire sutures. The danger from infection and the necrosis from this source is held to be extremely small when done under strictly aseptic conditions.

Puerperal Septicemia.—In the matter of prophylaxis there has appeared nothing new within the year. The well established principles governing complete asepsis are still rigidly insisted upon. The surgical cleanliness of the attendant's hands, arms and instruments and of the patient's external genitalia are matters of first importance. The antepartum and post-partum douche, as a matter of routine in normal labor, has been demonstrated to be an ineffective, unscientific and sometimes a dangerous procedure. In cases of manual delivery of the placenta or any other complication requiring the introduction of the hand within the uterine cavity,

douching of the vagina with a weak, hot bichloride solution, followed by an intrauterine douche of hot normal saline solution, is advocated by some excellent authorities, as a routine prophylactic measure. In France, and more especially in Paris, hypodermic injections of anti-streptococcic and anti-staphylococcic serum are regularly used as a matter of routine in prophylaxis, in those cases in which the membranes are ruptured when the patient enters the hospital. In this connection it must be observed that prophylaxis in private practice is evidently not as efficient as that in the hospital. It is readily recalled that prior to the introduction of antiseptic methods, the death rate from puerperal septicemia in hospital practice was truly appalling. Now it is almost nil, while that in private practice is yet quite appreciable. This will admit, of course, of but one explanation—a lack of detail and thoroughness in methods and means of securing asepsis on the part of the general practitioner in some instances and of its total disregard on the part of the ignorant and untrained midwife in all instances.

The observation of the writer would lead him to infer that the average general practitioner is sometimes prone to do hurriedly and superficially that which should be done thoroughly and deliberately in matters pertaining to asepsis. As to the uneducated midwife, it is truly unfortunate that so many unsuspecting women, especially in our larger centres of population, should be subjected to the contaminating touch of these carriers of infection; but existing social conditions would seem to indicate that it is nearly impossible to eliminate this element of danger, and that in all probability it will continue to flourish for some time to come.

Treatment.—All treatment has for its object the immediate destruction of micro-organisms of an infectious character already present within the vagina and uterine cavity, and the arrest of their further development on any of these surfaces. To this end a variety of measures are in vogue, in none of which, however, does repeated curetting or intrauterine douching with powerful germicidal agents have any longer a place. Some observers insist that it is unscientific to institute any form of treatment until a bacteriological examination of the vaginal discharge shall have been made, and contend that the time consumed (twenty-four hours) is more than offset by the information gained. Others again, whose results are invariably just as good, take an entirely different view and are of the opinion that the time consumed in making the culture would be much more profitably spent in combating the disease. These would treat every case as one of true septicemia, and if sapremia only, a cure is promptly effected. Disinfection of the vagina, exploration of the uterine cavity for remnants of placenta and decidua, and their prompt removal when present, douching of the intrauterine cavity with normal saline solution at a temperature of 110 degrees or 112 degrees, or with boric acid solution, or one-quarter per cent. formalin solution, packing with iodoform gauze, the introduction of iodoform pencils, the introduction of two large-sized catheters within the uterine cavity and left *in situ*, through which to

irrigate and drain, or a combination of some of these measures would seem to be the line of treatment to be followed at present. These measures failing, the opening of Douglas's cul de sac and drainage with iodoform gauze according to Pryor, of New York, is advocated. If the invasion of staphylococci or streptococci becomes systemic, recent contributors are agreed that hysterectomy can promise but scant relief, and in the minds of some is a questionable procedure in any case.

It has been observed that in some cases of true septicemia the intravenous injection of normal salt solution has a most pronounced and beneficial effect. Serum therapy, while extensively used in France, has been demonstrated to be entirely valueless in mixed infection and may be said to be still in the experimental stage.

Ectopic Gestation.—The consensus of opinion, as gleaned from the published statements of numerous observers throughout the year, would unquestionably indicate that ectopic gestation is a complication of much more frequent occurrence than was formerly supposed. And when, in addition to this, it is equally true that in the vast majority of instances, these patients first come under the observation of the general practitioner, it is at once apparent how essential it is that he draw the line sharply between a passing functional disturbance and a condition of such magnitude as may ultimately, and frequently quite suddenly, destroy the life of his patient. As one writer tersely puts it, "the general practitioner must be on the lookout for it," otherwise he will most likely overlook it at a stage when prompt surgical intervention would be in itself practically devoid of danger and would cure his patient, while a little later it would not only be extremely hazardous, but sometimes absolutely useless as well. The responsibility of the general practitioner becomes all the more pronounced in view of the fact that it is conceded that in the majority of instances ectopic gestation is attended with a fairly uniform symptomatology. It is to be observed, however, that while this is doubtless true in the main, it frequently happens that the patient herself has no suspicion that there is anything seriously wrong beyond the fact that she may be normally pregnant; and therefore fails to seek advice until suddenly some alarming symptom, as excruciating pain or excessive bleeding, arises. And, again, even when the symptoms are of a character which prompt her to obtain medical advice, the differential diagnosis between ectopic gestation and some other pelvic disorders is attended with the greatest difficulty, and, as above stated, unless the physician be on the lookout for this, he may, even after a physical examination, be led into the false position of a diagnosis of normal pregnancy. This is more particularly likely to occur in those cases in which a normal pregnancy is coexistent with an ectopic gestation. From the standpoint of the general practitioner, it is not necessarily essential that a positive diagnosis be made in many of these cases, nor, indeed, can there be, but from the character of the literature already available, it would seem that the time is fully past that would excuse him in

mistaking the symptomatology of this condition for colic, dysmenorrhea or ovarian congestion.

Diagnosis.—In this connection the points especially emphasized, are a previous history of sterility, a sudden cessation of a previously regular menstrual history, irregular but not excessive uterine bleeding, sharp colicky pains occurring at rather frequent but irregular intervals, and in not a few instances nausea and vomiting such as occur in normal pregnancy; with every such history it is insisted upon that a bimanual examination should at once be made, an anesthetic being used when necessary. The points here emphasized by every observer are the presence of a slightly enlarged uterus, a soft cervix, and the presence of a tender, more or less globular mass to the right or left of the uterus well up in the pelvic cavity. A pyo-salpinx or a tubo-ovarian abscess are the two pathological conditions with which ectopic gestation is most likely to be confounded.

Puerperal Eclampsia.—It is entirely safe to say that no purely obstetrical subject has been accorded more attention during the year than the symptom-complex, known as eclampsia. As to its etiology, writers are agreed upon a single point only, viz., toxemia. Beyond this there would appear to be considerable difference of opinion. If we are to be guided by the judgment of some, we should infer that the specific cause of eclampsia has been unquestionably isolated, and that any further search in this direction would only be a waste of time and energy. To such belong those who declare positively and unequivocally that urea or one of its synthetic compounds is the one great and primal cause of eclampsia. These observers declare that the teaching that the uremic state is always associated with casts and albumen is not only all wrong but positively dangerous as well. They assert that even in the presence of edema and headache, if no albumen be found, it frequently happens that the attendant pronounces his patient safe and free from peril. They contend, furthermore, that the toxemia of pregnancy, the pre-eclamptic state and eclampsia, are always associated with kidney inadequacy in so far as the absolute diminution of excreted solid elements is concerned; and that conversely, a return to the normal of the solid elements, especially urea or its congener nitrogen, is almost always curative of the toxemia of pregnancy, the pre-eclamptic state and eclampsia; and moreover that a due regard on the part of the medical attendant for the amount of urea excreted will be attended in almost every case with what would otherwise be the true eclamptic state. The reasoning of these observers would appear logical, convincing and conclusive, and yet, immediately in the wake of such reasoning, we are reminded by other investigators, within the last two months, that the urea theory of eclampsia has been entirely exploded, and that beyond the fact that eclampsia is consequent upon a toxin in the circulation as the outcome of the state of pregnancy, nothing is or can be definitely known, at this stage of investigation, and they contend that in all probability the liver, skin and intestinal canal in many instances play an important part in the production of the toxin. To the

personal knowledge of the writer, but a solitary observer has felt sufficiently sure of his ground to announce that the cause of eclampsia is clearly demonstrable on the post mortem table; and is equally positive as to the source of the toxin and considers it to be threefold; first, the placenta; second, the fetus; third, the alimentary canal. He maintains with others that the pre-eclamptic stage is caused by the presence of toxins in the circulation; the essential lesion of which consists of minute capillary thrombi with hemorrhagic infections, surrounded by tissue necrosis. This lesion is demonstrated to be of the same character in the brain, liver, kidneys, lungs and spleen, and that the toxins produce the coagulation of the blood and the thrombi, and when this occurs, eclampsia supervenes. While this view of the pathology of eclampsia may be fairly constant, it might be just as logical to conclude that the lesion described was consequent upon the eclampsia rather than that the eclampsia was consequent upon the lesion. Beside from the toxemia it is generally conceded that loss of sleep, depressing mental emotion, an irritable uterus and an excitable nervous system may be either individually, or collectively, contributing factors in the production of eclampsia. The contagiousness of eclampsia has been mentioned by one authority only, who considers it a self-limiting infectious disease—contagion being air-borne and affecting women in the puerperium only. In the matter of prophylaxis, we find much more unanimity of opinion, and the high ground is taken that eclampsia is largely a preventable complication, even more so than puerperal sepsis; and that prophylaxis presupposes the intelligent supervision of the patient from the earlier months of pregnancy, with a special reference to sanitation, food, etc.

Treatment.—The pre-eclamptic state, as evidenced by scanty urine, dizziness, headache and epigastric pain, is to be met by milk diet, cathartics and diuretics and the ingestion of large quantities of fluids. In the matter of treatment of the attack, venesection is less extensively practiced than formerly and is esteemed of especial value in the plethoric cases only. The same may be said of veratrum viride, which has been so greatly extolled by those who were disposed to regard it almost in the light of a specific. Morphia and chloroform are both highly commended and, singularly enough, each is condemned in the most outspoken way by the advocates of the other: chloroform, because of its interference with the already greatly embarrassed respiration; morphia, because it paralyzes all the emunctories, except possibly the skin. Notwithstanding these objections to these agents, it must be conceded that in each of them we have a most valuable and powerful weapon for the control of the convulsion. Hypodermoclysis, enteroclysis and direct intravenous infusion are uniformly commended and advised, and can be used in conjunction with any of the other therapeutic measures, and, when time is afforded, should be used in every case of eclampsia. If the patient be at the term a full hot bath is esteemed serviceable in favoring uterine dilatation and as sedative to the greatly excited nervous state. Rapid dilatation, even by

incision, according to Dührson, has still some advocates but would appear to be rarely practiced, and is being displaced by Cesarean section, as affording more real safety to both mother and child in cases in which emptying the uterus becomes immediately imperative. Sodium bromide and chloral hydrate in large doses per rectum, in conjunction with morphia and chloroform, are still in favor and are extensively used at home and abroad. Serum therapy of eclampsia is regarded as a problem of the future.

The Treatment of Epithelioma with Arsenic in Ethyl Alcohol.—S. Czerny (*Gazeta lekarska*, April 21, 1901; *Vratch*, Vol. XXII, No. 19) recommended in 1897 the application of alcoholic solution of arsenic to cancers of superficial parts of the body, such as the nose, lips, ear, tongue, breasts, etc. Since then he employed this method in a large number of cases with excellent results. The solution is made up by adding 1 grm. of powdered arsenic to 100 c.c. of 50% alcohol. The applications are made daily. After the first application the patient experiences a slight pain which may be relieved by a 10% solution of cocaine or orthoform. On the following day a dry scab forms which gradually extends and finally drops off. The affected tissue is turned black by arsenic while the healthy structures are covered by a yellowish crust, thus offering means of differentiation. Small ulcers may be entirely cured in 2 to 4 weeks [A. R.]

\$3.00 PER ANNUM

The Official Report of President McKinley's Case.

—The final report by the medical staff attending the late President leaves no hiatus. A study of the brief but very clear notes on all the details of the case from the beginning to the end gives a perfect retrospect, and no one can find grounds upon which to base ex post facto objections. A clinical retrospect may often furnish most convincing evidence of errors in judgment in the conduct of a case, but with the surgeons' and pathologists' reports before us we are unable to see how the President could have been more scientifically treated.

From the moment he was taken in charge by the ambulance surgeon until the fatal termination one week later the best surgical judgment was shown. That the sanguine anticipations of the attending staff were not justified is now self-evident, but in view of the favorable clinical notes, with the one exception of the pulse rate, which continued until the hour of the sudden change for the worse, a favorable prognosis was justified. No time was lost in beginning the operation. The assassin's bullet was fired at 4.07 in the afternoon. At 4.18 the distinguished patient was placed upon the operating table and undressed. The President's wounds were inspected by Dr. Mynter at 4.45 who at once recognized the urgent necessity for operation, and upon the arrival of Dr. Mann, who was chosen to do the operation, the administration of the anesthetic was begun. The operation was commenced at 5.29 and the seats of injury in the stomach walls were expeditiously located. With the exception of the deficient illumination and the difficulties incident to the lack of abdominal retractors, the operation was conducted without complications and with the greatest celerity and precision. The only point which furnished ground for possible criticism was the closure of the wound without drainage. Without question the great majority of surgeons are in full accord with the course pursued by Dr. Mann, for, as stated by him at the time of the operation, and concurred in by his associates with one exception, drainage appeared to be unnecessary. Again, the results of the autopsy

would appear to justify this decision, for notwithstanding there were a few spoonfuls of greenish, gray, thick fluid beneath the mesocolon, the most efficient drain would probably not have reached this spot. In the final criticism of the operation we, therefore, are in entire concurrence with the great majority of European and American surgeons in giving to Dr. Mann and his associates unquestioned credit for the skilful way in which the operation was conducted. This endorsement is fully justified by the autopsy notes, for they reveal nothing which in any way casts reflection upon the surgical treatment of the case.

As to the conduct of the autopsy, criticism might be offered were it not that the pathologists were forced to curtail a fully detailed examination. The failure to locate the bullet was of little moment, but a careful microscopic examination of all organs and involved tissues might have thrown light upon some of the questions which now must remain dark. The notes bearing upon the macroscopic changes in the pancreas appear to be of vital importance. While our knowledge of surgical diseases and injuries to the pancreas is very deficient, we nevertheless know that in certain acute infections there are symptoms of great depression characterized by rapidity of the pulse and rapidly increasing lethal symptoms. The slight traumatism of the kidney was of little importance in the case. It would appear possible that the impaired condition of the kidneys, as demonstrated by the urinary examination and pathological report, taken in conjunction with a greatly weakened heart, rendered the President especially vulnerable to a terminal toxemia. Such toxemias are usually of bacterial origin, but as the bacteriological report fails to demonstrate any serious infection we are forced to fall back upon the theory that the toxic products incident to the necrosis of the pancreas and surrounding tissues through their absorption, may have been sufficient to have contributed to the fatal termination.

This, however, is a matter of speculation, for we have no well defined basis for this theory. That the final symptoms were not due to the usual complications of abdominal section is certain. It is to

be hoped that carefully conducted experiments bearing upon the surgical lesions of the pancreas will be carried out.

Gastric Wounds and Septic Gangrene.—An esteemed contributor has suggested in an interesting letter that, if the contused and locally shocked tissue immediately surrounding the gastric wounds had been cut out before the sutures were applied, the President might have recovered, even though gangrene of the tissues back of the stomach subsequently occurred; because the latter condition might have been relieved by a later operation and drainage.

The answer by abdominal operators to this query would be, that in wounds of the stomach and intestines the edges are never applied to each other, as in the wounds of the skin, but are turned inwards towards the cavity of the viscus by some form of suture like that of Lembert. This method causes the external or serous surfaces to come together, gives rapid adhesions, and inverts the damaged tissue, at the margin of the wound, into the stomach or bowel, where it does no damage.

An additional reply, however, may be found in the official report of the President's case, published last Saturday in this journal. This says: "The original injuries to the stomach-wall had been repaired by suture, and this repair seems to have been effective. The stitches were in place, and the openings in the stomach-wall were effectively closed." The gangrene surrounding the wounds is seemingly attributed to lowered vitality. The report also shows that death did not come from these comparatively small gangrenous spots in the gastric wall, but from the larger areas of gangrene behind the stomach and about the pancreas and upper end of the kidney.

In the editorial on "Traumatic Surgery of the Upper Abdomen," published two weeks ago, a statement was made that the President's death was probably due to septic gangrene, due to the missile. This was written without any accurate knowledge of the results of the autopsy. The official report, now given to the public, says that a conclusion is warranted that bacterial infection was *not* a factor in the production of the conditions found at the autopsy.

This statement deserves great respect, because of its eminent authorship and its truly scientific wording. Does it not seem possible, nevertheless, that the gangrene *did* occur as a result of bacterial contamination from gastric contents liberated by the bullet or from the bullet itself? The necrotic part of the posterior wall of the stomach lay in contact with the surface of the meso-colon; the portion of meso-colon "coming directly in contact with the wound in the gastric wall being of a dull gray color."

This looks like secondary infection by contact. Beyond the wound in the back of the stomach was a gangrenous track evidently indicating the course of the bullet. It is stated that here "very few micro-organisms were found in the fresh state." This seems to mean that the tissues and fluids were not entirely sterile. In the necrotic cavity a short, stumpy bacterium was found which, it is true, may have been due to a suggested technical imperfection in making the cultures.

These points would probably lead the ordinary clinical observer to attribute the death of the patient to septic gangrene. He would, however, not fail to realize that the necrosis might have arisen from injury to deep blood vessels, caused by the undiscovered bullet, and to imperfect blood supply in the stomach walls, due to the necessary operative detachment of the omentum. He would also lay proper stress on the fact that defective tissue resistance in a patient with unsound kidneys and a fatty heart renders disastrous results more likely from a moderately virulent micro-organism or a moderate disturbance of circulation.

The Report of the Autopsy in the President's Case.—In our issue of October 19, 1901, there appeared the report of the case of President McKinley contributed by his attending physicians. This report was awaited with great interest by the profession, and indicates what has been remarked a number of times, that much of the criticism and comment made upon the conduct of the case might have been deferred with much better taste until the facts were laid before the profession as has now been done. The condition of the President's heart, as shown by both the macroscopic and the microscopic examination, indicates clearly, as was pointed out in our previous editorials dealing with this possibility, that the condition of this organ had a most important bearing upon the fatal outcome. The report of Dr. Gaylord mentions particularly the extensive brown atrophy and the diffuse fatty degeneration of the muscle, and calls attention to the extent to which the pericardial fat had invaded the atrophic muscle fibres of the wall of the right ventricle. Dr. Gaylord remarks that this pathological condition explains, in part at least, the rapid pulse and the lack of response of this organ to the stimulants which were administered. The necrotic condition of the pancreas was a factor of uncertain power in the possible fatal termination. We are not in possession of sufficient facts to decide the precise amount of necrosis of this organ which is necessary to induce death.

On the superior aspect of the left kidney there was found a protrusion of the cortex, dark red in color,

and in this protrusion there was a laceration 2 cm. long, extending across the superior border, approximately at right angle with the periphery of the kidney, and from before backward. Dr. Gaylord gives it as his opinion that the wound of the kidney was of slight importance, save that it indicated the direction taken by the bullet.

The Bacteriological Report.—Dr. Matzinger, who conducted the bacteriological examination, succeeded in isolating from a culture, taken from the base of the abdominal wound, and from dressings received at the same time, ordinary pyogenic organisms and a gas-forming bacillus which as yet has not been fully identified. Until this identification is complete, speculation upon its possible pathogenic character appears useless.

The Cause of President McKinley's Death.—We have never altogether shared the opinion of those who professed to see an unsolved mystery in President McKinley's death, and since we have read Dr. Gaylord's report of the autopsy we are still less inclined to see any ground for mystification in that sad event. In our judgment the immediate cause of death was a degenerated heart muscle. The clinical progress of the case pointed to that condition, and the autopsy confirms it. We have pointed out from the first in these columns that the President suffered from the effect of shock—shock caused not only by the assault but especially by the operation. This was inevitable. It would have been so in the hands of any surgeon. The patient, as shown in the report, went on the operating table with a pulse of 84 and left it with a pulse of 124. His pulse never really rallied after the operation; it never, according to the bulletins, regained anything like a satisfactory tone. This was evidently because there was back of it a heart muscle which was undergoing fatty and granular degeneration. This is by no means the first case in abdominal surgery, in which such a heart has baffled the best skill.

The devitalization of wounded tissue under such circumstances is not a cause for wonder. Such tissue requires the best sort of blood supply for its repair: it cannot secure it from a debilitated and deteriorated heart muscle. Surgeons are more particular to ascertain the state of the kidneys than they are of the heart, and even in the case of the heart, the absence of a valvular lesion is supposed to be a guarantee of safety. This dictum is erroneous. The most serious affection of the heart in advancing years is a sclerosis of the coronary arteries and a degeneration of the muscle. These President McKinley evidently had.

The Case of the Assassin.—It is probable that before this number of the journal reaches all its

readers, the assassin of President McKinley will have paid the penalty for his foul crime. The case of Czolgosz is of distinct historic interest, and has a medico-legal importance perhaps greater than may at first sight appear to close contemporary observers. As the case recedes into the past the trial may assume unexpected proportions as a precedent in medical jurisprudence. Whether this will be for good or for evil, remains for the future to discover.

In recognition of the unique importance of the case we have taken pains to present, in these pages, some of the most authoritative opinions that are to be obtained in this country. Mr. Graham, the former District Attorney of Philadelphia, had, while in office, an extensive experience with criminal cases in which the defence of insanity was offered. He always conducted such cases for the Commonwealth with an earnestness of conviction and a force of eloquence that won the approval of the general public and the recognition even of those whom he opposed and who opposed him. His opinion, which we published last week, was of special interest from the fact that it referred to the one particular point on which there has been some tendency to criticize the conduct of the trial. This was the omission to submit any evidence whatever as to the prisoner's mental state. It has seemed to some critics that the record of the case would have been more complete, if the experts who examined the prisoner had been put upon the stand and submitted to cross-examination, even though their testimony had been entirely favorable to the prisoner's sanity. Mr. Graham shows, however, that the law presumes the sanity, just as it presumes the innocence, of the accused until the contrary is shown, and consequently that the burden of proof is on the defence, in the one instance, just as it is on the prosecution, in the other.

This is evidently one of those technical questions on which opinion is somewhat colored by the point of view. From the legal standpoint it is incontestable that Mr. Graham is correct, and from this standpoint the case at present is largely being judged. From the medical standpoint, the tendency of opinion seems to be that an exception to this rule might have been beneficial because of the magnitude and significance of the case. Of the prisoner's absolute sanity there has never been any apparent ground for doubt. As Dr. Dercum happily expressed it, the case belongs not to the psychiatry but to the psychology of crime. The papers which we publish this week, by Dr. Spitzka and Dr. Mills, are largely historical in scope and interest.

Honoring Virchow and Ourselves.—The Virchow dinner, held last week in New York was an affair far more significant than appears upon the surface.

Three things in this world secure the plaudits of the multitude: power and its companion, patronage; the ability to amuse, and an altruistic search for truth without hope for other reward than the recognition of having at least added a trifle to the slender but treasured common stock. What power Virchow possesses has come to him long after his work as a discoverer had been carried to such a point of perfection, that the mechanics of discovery (if we may so term the noisy workers who are capable, perhaps, of carrying an idea to a higher state of development than its originator, but utterly incapable of originating it themselves) were busily engaged in cutting sections, inventing stains and suggesting additions to, and modifications of cellular pathology in every medical centre of the world. What ability to amuse and interest us he has, is only that inherent to every sturdy and independent character; for neither society nor government has been able to make him recall or modify a single belief in either politics or science. What he has done for knowledge is that which only one can do who is gifted with the power to perceive order and design where others see only a hopelessly entangled maze. Without greed or self-seeking, anxious only for truth, eager to spread it as far afield as possible, Virchow has lived beyond the allotted span of life, true to himself, and as surely as night doth follow day, never false to his fellows. And hence it is that in another half of the world, as well as in his own, men have assembled to do honor to him, who all in all has been a man. Alas! we sadly need his like again.

Still More Plague.—The *Occidental Medical Times*, in a recent editorial, which we quote elsewhere, announces that the situation in San Francisco is "full of peril." Although the State Board of Health of California "has strenuously denied that there has been any plague in California, seven more cases have occurred;" this has been since August 31. The rainy season is on, and several thousand Chinamen are returning from the grain fields, orchards and canneries; hence the danger. The *Occidental Medical Times* declares in good round English that the State Board "stultifies itself by its false declarations."

It is satisfactory, if hard language must be used in this connection, to have the *Occidental Medical Times* use it. We remember to have drawn down on our devoted head last spring the maledictions of this good contemporary for having failed properly to distinguish who did the lying about the plague in California. By the aid of our friends (and possibly of some of our enemies) in that State, we have been enabled to fasten our contumely upon the State Board of Health. But as the Board is a political body, it will probably not care any more for our

contumely than it does for the plague. In the meantime it is just possible that the plague (which a delegation of San Francisco citizens came to Washington last spring to ignore) will keep right on. We are glad to note, however, that Dr. Ryfkogel and some other reliable men are at work on the subject.

Transplantation of the Ureters.—The interesting paper by Dr. A. Lapthorn Smith, of Montreal, on "Ureteral Transplantation," which appeared in last week's issue of this journal, touches upon one of the more recent advances made in abdominal and pelvic surgery. This operation is a rare one. In all surgical literature there are but ten such cases reported. Of these Dr. Smith's patient is the only one reported from Canada, while Penrose, Baldy and Fullerton have each performed the operation once in this city, following the method first suggested by Van Hook.

Kelly, of Baltimore, and Krug and Boldt, of New York, are the only other operators on this side of the water, who have been called upon to perform ureteral transplantation. This gives to American surgeons a total of seven out of the entire number (ten) of patients who have been operated upon, an excellent showing, and one that adds another star to the splendid record of American surgery.

The *Interstate Medical Journal*, of St. Louis, comes to us in its October number in improved form. Dr. O. F. Ball, the managing editor, has associated with him a staff of thirteen assistants, who are well qualified for bringing and keeping this publication well up to the required standard of first class medical journalism. We congratulate the journal and its subscribers.

Current Comment.

VIRCHOW.

While engaged in scientific researches, which in universality, novelty and reforming power, are surpassed or equalled by none that are immortalized in the history of medicine, Virchow never ceased to feel that he did not only belong to theoretical and practical science, but to his people; and moreover, while his theoretical work has always a practical bearing and result, so his political and social views have a practical tendency.

He was born one of the people, and remained a friend of the people. He need not turn politician, he was and is politician born. We in this our country are in frequent danger of forgetting that at one time at least, the most intelligent, wise and pure men of this nation were our foremost politicians. Without the controlling sympathy of the very best, the Constitution of the United States would not have seen the light. We have since descended sometimes, aye many times, to the fear that only a second-rate intellect and a third-rate morality make a successful and zealous politician, losing sight of the fact that Aristotle already defined man as a "political being" and insisted upon the labor of all in the interest of all.

Virchow's example should teach, particularly young

medical men, that thorough science and good citizenship do not exclude each other. Indeed there is nobody so removed from the midst of his fellows, so absorbed in abstract studies, that has no interests in common with the rest of mankind. To prove your sympathy, what you have to spend in time, in activity, in money, should be given to the cause of the people, in the town and in the country, and particularly in critical periods of our history, like that of to-day.—*Dr. A. Jacobi's address on Virchow.*

MORE PLAGUE.

Although the State Board of Health of California has strenuously denied that there has been any plague in California, seven more cases have occurred. Recently the State Board has ordered the local Board to raise its quarantine, which the latter has positively refused to do, thus, we hope, bringing the question of plague to a settlement in the courts. We believe, however, that the State Board will not force the issue.

As no measures of inspection, disinfection, or quarantine, except the tentative ones of the local Board, are being taken, our city and state are at the mercy of a possible epidemic. The local Board is and has always been severely handicapped by its financial condition, and the State Board yet stultifies itself by its false declarations. There is but one remedy, and we hope that will never come, though circumstances are propitious. The rainy season is on, and several thousand Chinamen are returning from the grain fields, orchards, and canneries. If history repeats itself, our position is full of peril. These eight cases, occurring early in the rainy season and having been found when determined efforts are being made to conceal them, and when no inspection is being carried on, and after the place has been cleaned and disinfected by the State Board under the supervision of the Marine Hospital service, does not render the situation in any degree inspiring.—*Occidental Medical Times.*

THE CASE WELL STATED.

We know that whenever a bullet passes through the living body it leaves a track of contusion, more or less well marked, according to the size or velocity of the projectile and the nature of the tissue which it traverses. If the patient survives the immediate injury, and recovery is a physiological possibility, the contused tissue undergoes one of two processes: If the bruise is not too severe and the patient's circulation is active, the tissue recovers. If not, it undergoes putrefaction or necrobiosis. Naturally, what in one patient with a good heart action and active vital processes would be a practically harmless contusion, in another with a weak and thin-walled organ would be exactly the opposite.

It is therefore not unreasonable to suppose that the necrosis tissue in the case of the President represented originally the contused tissue into which the enfeebled heart was unable to force the blood current so as to overcome the stagnation. This condition of affairs, associated with the feeble heart, again would explain the rapid pulse which was such a marked and ominous feature of the case, and which so sadly and effectually set at naught the optimistic predictions of some of the medical attendants.

The Medical Record.

WE ASTONISHED THE WORLD.

The Philadelphia Medical Journal, in an able review of the late President's case, incidentally states the effects of tobacco in language that is simply appalling to the lay mind. It says:

.. "The effect of tobacco is to cause nervous overaction, which will in time lead to a hypertrophic condition of the heart, owing to the extra work it throws on the organ. This hypertrophy in time naturally underwent changes of fatty infiltration and degeneration, and consequently dilatation. These may be accounted for by the increased obesity of the distinguished patient and the condition of arteriosclerosis, to be expected in a man of his years, and affecting to some extent the coronary arteries.

The effect of the long-continued general anesthesia is not to be overlooked. It has been shown quite conclusively that blood inspissation, a condition of anhydremia, is

present after etherization. The hemoglobin is reduced and a general hemolysis of varying degree occurs."

The average reader may not be able to mentally digest all this, but in a general way he will gather from it that tobacco is not a nerve food. Incidentally he will learn that doctors have a language of their own, well suited to express without explaining the "mysteries of medicine."

New York World.

INTERNATIONAL PREVENTION OF TUBERCULOSIS.

In an article in which he discusses the various means employed in European countries to check the spread of tubercle, Dr. S. Bernheim pleads strongly for an international prophylaxis. He points out that although tubercle differs in some points from cholera, yellow fever, and plague, it is nevertheless as important to combat it in the same international manner. Its bacillus is full of vitality, and is often carried across frontiers, and from country to country, in railway trains and ships. No isolated effort by any one nation can, therefore, hope to be successful. Bernheim recommends that the prophylaxis of tuberculosis be made the subject of international sanitary legislation, which could be fixed at some conference in the same way as the measures taken against cholera and the plague were decided upon. He specially refers to the good effects obtained by the tuberculin test in cases of bovine tuberculosis as carried out by Bang in Denmark: in certain parts of that country since the tuberculin test was adopted the percentage of animals that gave the reaction had fallen from 9 per cent. to 4.7 per cent. and even lower.—*British Medical Journal.*

Reviews.

Photographic Atlas of Diseases of the Skin. By George Henry Fox, A. M., M. D., Clinical Professor of Diseases of the Skin, College of Physicians and Surgeons, New York, etc. J. B. Lippincott Company, Publishers. Philadelphia and London. Parts I, II and III.

The admirable skill displayed by Dr. Fox in the photographing of cases of diseases of the skin, and his judgment in the selection of cases, are now too well known to the medical profession to need special comment. The first atlas was widely accepted. The excellence of his larger work more recently published and especially adapted for class teaching has been of advantage to his dermatological confrères. The present atlas is the physician's edition of the latter, the plates being smaller or quarto in size, but produced in the same excellent manner. The selections are good, and the coloring, upon the whole, satisfactory, and if the subsequent parts are kept up to the standard of the first three, now before us, the profession will have at its disposal another atlas of these diseases, which in the lack of clinical opportunities, can be studied with great advantage. In Part I are presented examples of ordinary acne of the face, erythematous eczema about the eyes, macular syphiloderm, herpes zoster, of side of chest, and dermatitis venenata. With the exception of the one of erythematous eczema, they are most excellent reproductions, and especially the last three which show most clearly common clinical types. Part II contains plates of acne of the back, pediculosis corporis, psoriasis (guttata), pityriasis maculata, and variola (two figures). These several are, like those of the first part, satisfactory representations, that of pityriasis maculata not being quite up to the standard of the others in the case selection or coloring. The other forms are admirable, especially those of smallpox, psoriasis and pediculosis. Part III contains plates of lupus erythematosus, lupus vulgaris, military papular syphiloderm, vitiligo, and lichen planus (two figures), which picture the disease quite clearly, the one of lupus erythematosus is not, however, up to the excellence of the others. In addition to the test explanatory of each plate, there is succinct but sufficiently full description of the therapeutics of the various maladies, more especially as to the methods employed by Dr. Fox himself. Together there is, therefore, presented a practical illustrated treatise on the subject, that can be cordially commended, and one which will be of service to those in general practice whose work brings them in con-

tact with cutaneous diseases, especially those who have not had previous clinical opportunities of acquiring the necessary knowledge for the proper diagnosis of these affections. [H. W. S.]

Manual of Chemistry. A Text-book specially adapted for students of medicine, pharmacy and dentistry. By W. Simon, Ph. D., M. D. 7th edition, 8vo., 591 pages and Index. Lea Bros. & Co. Philadelphia 1901.

This manual has been so long and favorably known, as is shown by the fact that the seventh edition is now before us, that an extended analysis of its features is hardly needed. One of its most striking characteristics, one that attracted much attention and discussion in the earlier volumes, is still prominent in the present issue, namely, the series of colored plates illustrating precipitates. We cannot deny the excellence of these, nor fail to admire the pains and skill which have been bestowed on the work, yet it is certainly open to argument as to whether such illustrations are necessary, when the actual preparation of the compounds is so easy, and under present methods of instruction required in most colleges. Dr. Simon's experience, has, however, led him to preserve this feature, and those who do not agree with him may, at least, rejoice that the method has been carried out with brilliancy and exactness.

As far as regards the general character of the book, it need only be said that it maintains the excellent position that it has held heretofore. The first part relating to chemical physics has been largely re-written, among the additions being a brief note on the modern theory of ionisation. Inorganic chemistry covers over two hundred pages, including some methods of analysis; organic chemistry, under the title "Chemistry of the Carbon Compounds" includes over one hundred and fifty pages, after which follow about one hundred pages devoted to "Physiological Chemistry," under which are included the important methods of clinical chemistry. In connection with the discussion of the coal-tar products we do note an explanation of the so-called benzene ring-symbol, now so much used in general literature, and so convenient for presenting the isomeric relations of these bodies.

A commendable feature is a table of known elements corrected according to the most recent data. On the question which is now under active discussion among chemists, namely the standard for atomic weight, Dr. Simon takes system $H=1$, but in the descriptive text both values are given in many cases.

The work is full of valuable information, is excellently printed and illustrated and is highly creditable to author and publisher. [H. L.]

The Principles of Hygiene. A Practical Manual for Students, Physicians and Health Officers. By D. H. Bergey, A. M., M. D., 8vo., 843 pages and Index. W. B. Saunders & Co., Philadelphia, 1901. \$3.00 net.

This is a comprehensive treatise on sanitary science, dealing with all the important issues in that field, in accordance with methods in general use. After a brief consideration of the principal causes of disease, the special sources of insanitary conditions are discussed in separate chapters. Among these are: Air, Ventilation and Heating; Water and Water-supplies; Disposal of Waste; Food and Diet; Industrial Hygiene; School Hygiene; Military and Naval Hygiene; Quarantine. It will be understood that the great mass of matter conforms to the principles of hygiene as laid down by the leading authorities, nevertheless the author has incorporated much that has been suggested by his own experience or evidences the bent of his mind. Some very important points of progress in recent years have been well presented and the book is well up to date without following every supposition that is conceding for recognition. Upon many points discussed in the book, sanitarians will be found in general accord; upon others differences of opinion will prevail. The reviewer is obliged to express dissent from some of Dr. Bergey's statements. The statement on page 223, that alcoholic beverages may be regarded as food by reason of the "extractives they contain" is misleading. While persons differ as to the methods by which the abuse of alcoholic beverages may be prevented, no intelligent and informed

scientist should even by inadvertence offer supposititious data that may encourage such abuse. As a matter of fact, one of the most used and most dangerous of beverages, whiskey, contains no nutritive extractives, and it is further very doubtful if the extractives of malt liquors are of any real value. Modern malt liquors are made with the aid of glucose, which contains no appreciable amount of nitrogenous matters, but does frequently contain much unfermentable carbohydrate of unknown physiological effect, and, therefore, as likely to be harmful as harmless. Serious errors have been made in the tables in the appendix. Factors for converting various data are given. Such factors should be reduced so that the necessary conversion may be made by one operation and that preferably by multiplication. Dr. Bergey gives methods of converting some data in water analysis, involving both multiplication and division, but these factors can be easily condensed to one requiring but a single operation. A more serious criticism is that many of the factors are quite wrong. Thus to convert nitrogen into nitric anhydride it is directed to multiply by 108 and divide by 14; the correct divisor is 28. The reverse procedure is also in error as well as the methods for conversion of nitrous anhydride. Several factors are given for the conversion of the gallon into parts per million and analogous data, but only the Imperial gallon is considered, while American chemists, physicians and pharmacists use almost exclusively the U. S. gallon, a very different measure. A cubic foot is stated to be 6.23 gallons; this again is the Imperial gallon; a cubic foot contains nearly 7.5 U. S. gallons. The printing of the work is satisfactory, but the highly surfaced paper is trying to the eyes, and the title page is in bad taste, suiting an obituary memoir rather than a work on science. The book is but sparingly illustrated. [H. L.]

Libertinism and Marriage. By Dr. Louis Jullien, Surgeon of St. Lazare Prison, etc. Translated by R. B. Douglas. Philadelphia, F. A. Davis Company, Publishers, 1901. Pp. 169.

This little volume contains an interesting and readable account of the methods of transmission of gonorrhea in the male and female by innocent and other means. It is suited only for professional perusal although doubtless it would make absorbing reading for those not in the medical profession. There is nothing in it in the therapeutic line, nor does the book contain anything of original value. As far as it goes the material is reliable, although it is a question whether some portions of unwritten medicine should not remain in obscurity. [W. A. N. D.]

Correspondence.

A CORRECTION.

By GEORGE S. GRAHAM, Esq., of Philadelphia.

Dear Sir:—In your publication of my comments upon the Czolgosz case, an error appears which I would like to correct. It may be my mistake in omitting two letters in the writing of the article; or, a typographical error on your part.

I am made to say "If the counsel had medical testimony tending to prove sanity and did not produce it to the jury," etc., whereas I should have appeared as saying "If counsel had medical testimony tending to prove insanity," etc.

The law presumes sanity in every person accused of crime. No evidence could be offered on the subject of the prisoner's sanity before it was assailed. The Commonwealth could not offer to prove affirmatively what the law assumed to exist. The prisoner's counsel would only be concerned to prove *insanity*, to rebut the presumption of law. One can readily see how inappropriate and senseless the language attributed to me in the article must be. If you will kindly place me properly before your readers, I will be grateful to you.

[Note by the Editor.—The error, which we greatly regret, was ours.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Society Meetings.—The Neurological Society of Philadelphia will hold its next meeting at the College of Physicians, upon Monday evening, October 28, 1901, at 8.15 P. M.

University of Pennsylvania.—Five appointments were made recently in the Department of Medicine by the trustees of the University, as follows: Dr. R. Norton Downs, Jr., assistant demonstrator of obstetrics, Drs. M. H. Biggs and J. B. Carnett, assistant instructors in surgery, Dr. Maurice Ostheimer, instructor in children's diseases, and Dr. C. C. Norris, instructor in gynecology.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1902, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the secretary of the college on or before May 1, 1902. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of the competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award. The Alvarenga Prize for 1901 has been awarded to Dr. George W. Crile, of Cleveland, Ohio, for his essay entitled "An Experimental and Clinical Research into Certain Problems Relating to Surgical Operations."

Leprosy in Philadelphia.—Wung Ta Sung, a Chinese laundry worker, at 6001 Westminster avenue, has what is pronounced to be a true case of leprosy. He presents a number of large skin lesions on his shoulders and back. The fact that the patient has been occupied daily in washing other person's clothing makes the discovery of the dread disease somewhat sensational, though there is little or no danger that any spread of the disease could be started in this way. (He left for New York before the Municipal Hospital physician had located him).

St. Luke's Hospital, Bethlehem.—St. Luke's day was celebrated at St. Luke's Hospital, Bethlehem, October 18th. Dr. Foster, editor of the *New York Medical Journal*, delivered an address, after which the Rebecca Nickley Thomas Memorial Pavilion was presented to the hospital. The medical society of Northampton county, which had been holding its annual meeting in Bethlehem, attended in a body.

Dr. Henri Hartman, professor of surgery in Paris, secretary of the Section on Gynecology at the Thirteenth International Congress last year, has been visiting Dr. Ernest LaPlace, professor of surgery in the Medico-Chirurgical College of Philadelphia.

Death of Dr. Hannah E. Longshore.—Dr. Hannah E. Longshore, the first woman to practice medicine in Philadelphia, died October 18th in the 83d year of her age. Death was due to nervous prostration. Dr. Longshore was born May 30, 1819, in Montgomery county, Maryland. She was the daughter of Samuel and Paulina Meyers, who had emigrated from this State, and were descendants of Edward and Eleanor Foulke, pioneer members of the Society of Friends in Philadelphia. During her early childhood her parents moved to Ohio, where they made their home on a farm, near New Lisbon, Columbia county, about 1833. At a very early period her interest in medical science was manifested by her examination and dissection of insects and small animals, and she pursued it with the care and accuracy that distinguish the thoughtful student. Not long after she began to study medicine, she married, at the age of 22. Six years later, when the younger of her two children was four years old, she resumed her favorite study. In this she was assisted by her brother-in-law, Professor Joseph S. Longshore, of Langhorne, Bucks county, Pa., who tendered her the use of his medical library, skeletons and great knowledge of medicine and surgery. Subsequently she entered the Woman's Medical

College of Pennsylvania, and was one of the ten members who comprised its first graduating class. She was immediately elected Demonstrator of Anatomy, and distinguished herself by being the first woman to put out her sign as a medical practitioner in Philadelphia. She made such a success during forty years of activity that she retired with a modest fortune, and it was said that her practice was larger, with one exception, than that of any other woman physician in the United States. She is survived by two children. Dr. Longshore's manner was characterized by entire simplicity in speech and dress; always unpretending, yet assured in judgment.

Vital Statistics of Philadelphia for the week ending October 19, 1901:

Total mortality	401	Cases.	Deaths.
Inflammation of the appendix 5, brain 19, bronch 11, heart 1, kidneys 25, liver 3, lungs 37, peritoneum 5, pleura 1, stomach and bowels 13, uterus 1			121
Marasmus 23, inanition 20, debility 6			49
Tuberculosis of the lungs			38
Apoplexy 12, paralysis 7			19
Heart-disease of 30, dropsy of 2, fatty degeneration of 3, neuralgia of 3			38
Uremia 3, Bright's disease 7, diabetes 2			12
Carcinoma of the face 1, breast 1, stomach 4, uterus 2, liver 6, neck 1			15
Convulsions			10
Diphtheria	71		7
Brain, dropsy of 1, softening of 1 ..			2
Typhoid fever	78		11
Old age			6
Scarlet fever	57		2
Smallpox	69		10
Abscess of the stomach 1, alcoholism 2, asthma 2, anemia 1, burns and scalds 4, casualties 12, cholera infantum 3, cirrhosis of the liver 2, cyanosis 4, diarrhoea 2, dysentery 2, gangrene, leg 1, hemorrhage from stomach 1, hernia 2, jaundice 3, shock, electric 1, sclerosis, spine 1, shock, surgical 2, septicemia 1, sarcoma, jaw 1, sarcoma larynx 2, suffocation 3, starvation 1, tumor, ovarian 1, ulceration of the stomach 1, unknown coroner cases 2, whooping cough 3			61

NEW YORK AND NEW JERSEY.

The New York Pathological Institute.—The plan of reorganization of the Pathological Institute of the New York State Hospitals for the Insane, undertaken by the State Commission in Lunacy, is gradually taking shape. It is the aim of the reorganized institute to carry on work in the sciences correlated with psychiatry. Original research in the various sciences bearing upon insanity will continue, and the institute will be utilized for special instruction in clinical psychiatry and methods of scientific research for physicians in the hospitals for the insane. The institution will use one of the asylums on Ward's Island until a reception hospital for the insane can be established in Manhattan. The Commission in Lunacy has established an advisory board, consisting of Drs. J. M. Cattell, professor of psychology, Columbia University; James Ewing, professor of pathology, Cornell University; C. A. Herter, professor of pathological chemistry, Bellevue Hospital and University Medical College, H. C. Bumpus, assistant to the president of the American Museum of Natural History; Henry Hun, professor of nervous diseases, Albany Medical College; C. W. Pilgrim, superintendent of the Hudson River State Hospital at Poughkeepsie; A. E. MacDonald, superintendent of the Manhattan State Hospital, East; and Frederick Peterson, president of the Lunacy Commission, ex-officio. All but two of the appointments are permanent, the two superinten-

dents of asylums being elected for two years only. All selected have accepted their appointments.

New York Obstetrical Society.—At the annual meeting of the New York Obstetrical Society, held October 8, 1901, the following officers were elected for the ensuing year: President Dr. Malcolm McLean; first vice president, Dr. J. Riddle Goffe; second vice president, Dr. LeRoy Brown; recording secretary, Dr. George L. Brodhead; assistant secretary, Dr. George G. Ward, Jr.; corresponding secretary, Dr. E. E. Tull; treasurer, Dr. J. Lee Morrill; pathologist, Dr. W. S. Stone.

Cigar Stumps and Disease.—In Jersey City, New Jersey, policemen are trying to prevent the gathering of cigar and cigarette stumps by Italians who make new cigars and cigarettes out of them. This practice, which is especially prevalent in Jersey City, is considered by the Board of Health to be the cause of the spread of certain diseases, especially tuberculosis and cancer.

Camden Municipal Hospital.—The Camden Board of Health has concluded negotiations for the site for the erection of a temporary municipal hospital. It is supposed that the building will be erected on land of the Camden Cemetery Association. At present the eight patients with smallpox are kept in an empty house rented by the Board of Health. There has been but one other suspicious case reported in Camden.

Hospital for Contagious Diseases Burned.—The Common Council of the city of Elmira, N. Y., purchased a house and lot to be turned into a detention emergency hospital for contagious diseases, in spite of the opposition of the residents of that section of the city. On October 12th the house was burned to the ground.

NEW ENGLAND.

The New Faulkner Hospital.—Near the outskirts of Boston, a hospital for the poor inhabitants of Jamaica Plain, Forest Hills, Roslindale, and West Roxbury is being erected, in accordance with the regulations provided by the will of the late Mrs. Abby Faulkner. The ground left by Mrs. Faulkner consists of between six and seven acres. Work has already begun upon the administration building and one of the ward buildings, which will accommodate 30 patients. The hospital, which will be modern and well equipped, will represent an investment of almost \$100,000.

Boston Camp for Consumptives.—As soon as the weather will permit and proper locations can be selected, there will be pitched near Boston the first of a number of camps for consumptives. This camp (and each succeeding camp will be like it) will consist of ten piano box tents, arranged in a circle with an open air fire in the centre, and surrounded by a duck wall eight feet high. Each of these tents will be a consumptive's home; a consumptive will sleep there, even through the coldest weather, with no other protection than plenty of felt blankets, felt sleeping boots and a two gallon jug of hot water.

WESTERN STATES.

The Healthiest Town in America.—The most healthful place in the United States is Marion, Ia., according to reports received by the Marine Hospital Service from 1,190 cities and towns having a population of 1,000 or more. There may have been a more healthful place than Marion, but no official returns were received from it. Marion has a population of 4,100, and there were only six deaths in 1900, making the death rate the phenomenally low figure of 1.46 per 1,000. The average death rate in all the cities and towns was 17.47. The State having the best record for health last year was North Dakota with a death rate of only 6.95 per 1,000 of population. By far the most healthful of the very populous States, however, was Iowa, the death rate being 11.17. Ohio, which made reports from towns aggregating a population of more than a million and a half, shows a death rate of only 14.84. The notable reports of healthfulness, however, come from the Northwest and far Western States. Minnesota, the Dakotas, Nebraska, Kansas, Iowa, Idaho and Montana, all have exceedingly low death rates. On the other hand, the States which are widely known as health resorts, such as Arizona, Colorado and California, have a comparatively high mortality, probably because many persons suffering from incurable pulmonary troubles go there and die. California last year had an average death rate of 17.63, Colorado 25.29 and Arizona 32.28. The last-named had the highest mortality of any State or Territory in the Union. New

York State's mortality was 19.35. The town in the United States having the highest ratio of mortality last year was Carlyle, Ill., where the death rate was 53.31. The most unhealthful of the very large cities was Washington; death rate 21.71. Baltimore's death rate was 21.02, Philadelphia's 19.38, Boston's 20.82 and Chicago's 14.68.

Smallpox in Wisconsin.—It was reported last week that seventy-one cases of smallpox exist at the Odanah Government School, on the Bad River Reservation. An investigation shows that of seventy pupils boarding at the parochial school, forty-eight are infected. The district schools have been closed, and the reservation doubtless will be quarantined.

The University of Michigan.—The corner-stone of the new medical building of the University of Michigan was laid at Ann Arbor, October 15th, Dr. John A. McCorkle, of Brooklyn, who delivered an address.

Virchow Banquet in St. Louis.—The physicians of St. Louis met at a banquet at the St. Nicholas Hotel, Tuesday, October 15th, in honor of the eightieth birthday of the most celebrated living physician, Rudolph Virchow. Dr. Robert Luedeking was toastmaster and speeches were made by Drs. Hugo Summa, Willard Bartlett, Amand Ravold, Robert Terry and Mr. Perry Post Taylor.

Rudolph Virchow Honored.—In the "Kommers" which closed the meeting in honor of the 80th birthday of Prof. Rudolph Virchow at the Republican House, Milwaukee, Wis., Saturday night, October 12th, addresses on the great scientist and statesman's life were made by Edward A. Birge, acting president of the University of Wisconsin, Mayor David S. Rose, Gen. F. C. Winkler, Prof. Emil Dapprich, Dr. Ernst Voss of the University of Wisconsin, and Prof. L. R. Parker of the University of Chicago. Emil von Schleintz acted as toastmaster. Prof. Dapprich spoke of the breadth of Virchow, of his work as a teacher and in medicine, and the application of his knowledge and discoveries in science for the improvement of the common lot of mankind. Dr. Birge referred to the German scientist's achievement in organizing facts of science so that they could be understood and applied. Virchow had applied them to the benefit of municipalities as well as medicine and other sciences. Mayor Rose said that Virchow's perfected sewerage system of Berlin has been copied all over the world. The flushing tunnel in Milwaukee owed its existence to Prof. Virchow. Gen. Winkler spoke in German. He said that Virchow had won first place among statesmen of the world. Prof. Parker recounted several amusing incidents in the life of the scientist. A silver loving cup, ten inches in height, and inscribed with the fac-simile signatures of its donors, will be sent to Prof. Virchow this week. There are four local physicians who have studied under him—Drs. Gustav A. Kletzsch, Horace M. Brown, Arthur J. Puls and Otto Thlenhaus, Dr. Thlenhaus having been under him for five years. Over a hundred physicians attended the banquet.

Infirmery for Consumption.—A tract of twenty-five acres near Elysian Park, Los Angeles, has been purchased and \$7500 raised for the purpose of establishing an infirmery dedicated to the use of the indigent tuberculosis patients of Los Angeles. The promoters of this charitable object will build the first cottage at once. The infirmery will be erected on the cottage plan and maintained by private subscriptions.

CANADA.

(From our Special Correspondent.)

Infectious Diseases in Public Schools.—The need of daily inspection either by the teachers or physicians appointed by the local board of health is a question now being discussed in Toronto. If this is brought about, it will be on a line with similar work carried out in New York, Boston and Chicago. The scheme has already been endorsed by the Ontario Board of Health, and the only objection seems to be the matter of expense.

Queen's University.—During the opening exercises of the medical department of Queen's University, Kingston, Principal Grant sent a message to the students, urging them to take the study of medicine as seriously as divinity students study for the ministry. In his letter, he says: "I pledge myself to do more for the faculty and for the hospital than ever before. . . . As for yourselves, for the sake of all that is noble, and worthy, take your profession seriously from the outset. . . . It is awful to think that men, women and children should be at the mercy of irreverent and half-taught young doctors. I pledge myself,

that hereafter, for your own sakes, and for the sake of humanity, I shall try to let no such students pass our examinations."

Medical Students are Becoming More Numerous in the Province of Ontario.—In Trinity Medical College more students were registered, in the first year class on the opening day, than had been registered within the last twenty years. At the Toronto School of Medicine, the Dean announced that the freshman class was greater than ever before. As evidence of the way in which the numbers have increased, the records of the last four years tell an interesting tale. In the fall of '97 61 first year students were in attendance; in '98 73; in '99 104; in '00 124. If this increase continues, the question of a higher standard of matriculation will have to be considered in the immediate future.

Reports from Ottawa are serious regarding the prevalence of smallpox and other infectious diseases. The Medical Health Officer is away, and Dr. Law is looking after the health of the city in the meantime. Three or four cases develop daily, and since Sunday the 6th inst. twenty-three cases have appeared. Special constables have had to be appointed to see that quarantine is strictly carried out, and Dr. Law has advised closing the public schools and general vaccination. Dr. Bryce, Secretary of the Ontario Board of Health, has been summoned to the Capital, as there is understood to be a good deal of friction among members of the health board. A special order has been issued by the Minister of Public Works to the heads of all branches in his department, ordering vaccination at once. Sir James Grant is fearful that there will also be an epidemic of typhoid, owing to low water in the Ottawa River.

Montreal is Guarding Against the Invasion of Smallpox both from Ottawa and St. Henri, one of her own suburbs, where the disease already exists. The Quebec Board of Health has issued a general call for vaccination, and points out that the Ottawa outbreak renders it necessary for all municipalities to prepare to fight the disease. A special hospital is being established in Montreal, and in the meantime persons in the infected houses in the suburbs are being vaccinated and special quarantine officers placed on guard over them. Dr. Laberge, Medical Health Officer, and Dr. Pelletier, secretary of the Quebec Board, state that the outlook is serious. The Civic Hospital, which was designed for smallpox patients, is full of other cases of infectious diseases, so a special hospital is being hurriedly improvised to meet emergencies.

The Toronto Clinical Society held its first regular meeting for the season on the evening of October 2d, with Dr. J. F. W. Ross in the chair. Dr. Bruce showed the specimen of a hairy tumor from the stomach of a young married woman of 26, which he showed at the Canadian Medical Association meeting at Winnipeg, a report of which has been published in the columns of the *Philadelphia Medical Journal*. Dr. A. A. Small showed a woman with a cystic tumor in the left popliteal space, which was either growing from a tendon sheath or from one of the bursae; and another case of supposed polymastia, the supernumerary gland being situated on the back, close to the right posterior axillary line. The tumor was very characteristic and occurred in a woman of sixty who had borne several children, although the breast never showed any enlargement during lactation. The nipple had always been present, but the balance of the gland had developed within the last five years. There were no openings on the surface of the nipple. The consensus of opinion seemed to be that this was a lipoma, although remarkably like the female breast. Dr. A. A. Macdonald showed a cystic adenoma, which he had removed with a breast. A point of interest in the case was that the cyst had developed in eight weeks.

The Toronto Medical Society held its first meeting for the season on the evening of October 3d. Dr. F. N. G. Starr occupied the chair, and delivered a very interesting address on the deceased members of the profession in Toronto since the time when the city was known as the "muddy town of York." Mr. J. H. Cameron showed several specimens of calculi. In one case he secured fourteen small calculi in the cul-de-sac behind the prostate, by high section, from an old man of 76. Dr. Graham Chambers showed a girl of thirteen, the subject of hydroa vacciniformis for the last ten years. The patient exhibited sev-

eral scars, which simulated pock marks. Drs. Primrose and Chambers presented a patient, a young man of twenty-five, afflicted with blastomycosis. Two lime light views showed the warty outgrowths situated on different parts of the patient, one being on the right malar bone, another on the right shoulder, another on the neck, and still another at the inner canthus of the right eye, the latter being very like an epithelioma. Dr. Primrose excised portions of these growths and applied the actual cautery with success. The fungus was readily found under the microscope.

The Ontario Board of Health held its regular quarterly meeting in Toronto last week. The Secretary, Dr. Bryce, made a report upon smallpox, tuberculosis, and the question of the propriety of the Dominion Government founding an Institute for Scientific Research. His report upon smallpox showed that there had been, during the nine months of this year, 1064 cases of smallpox, the largest outbreak in Ontario in the history of the Board of Health, with only six deaths, a mortality of less than one per cent. Since the first of October some forty cases have been reported, principally from Ottawa, Oxford County, Manitoulin Island, and the County of Algoma. Referring to the subject of tuberculosis, he advised that municipalities should prohibit expectoration in public places, and that physicians be compelled to register all cases of tuberculosis. He considered that the time was opportune for the Dominion Government to commence the manufacture, under the Department of Agriculture, of vaccines and anti-toxins.

Notre Dame Hospital, Montreal, held its annual meeting last week. The reports were so encouraging, that it was decided to erect a new building and a site will forthwith be selected. During the past year 2,200 sick cases have been treated, an increase of 177 over the previous year. Two thousand and eighty-three of the patients were Catholics, and 117 Protestants. The cost for each case was ninety cents per day, a decrease of eight cents in comparison with the year before. Of the total number of cases treated, 1,854 left the hospital cured or convalescent, 155 were not improved, while 134 died, making the percentage 6.09, 79 of these cases being brought to the hospital in a precarious condition. In the dispensary there were 20,078 consultations, a decrease of 1,740 in comparison with the previous year. The financial part of the report states that the receipts amounted to \$32,293, while the expenditures amounted to \$29,480.51, leaving a surplus of \$2,812. Dr. E. P. Lachapelle was elected superintendent and Dr. Benoit, secretary.

Rockefeller Research Fellowship.—Professor W. M. Ford, of Johns Hopkins University, has been awarded the Rockefeller Research Fellowship, in pathology, of McGill University, Montreal. Dr. Ford is at present at work in the Pasteur Institute in Paris.

MISCELLANY.

Singers' Nodules.—Nodules the size of a pin's head have been noticed upon the vocal cords of singers, and are known by the name of "singers' nodules." These are described by Dr. Chiari as consisting of hypertrophied epithelium and connective tissue, occasionally containing dilated blood-vessels but without any trace of glandular structure. Much confusion has arisen in regard to these nodules, chiefly from the want of a clear definition of what was meant by the term. Anything in the nature of a growth which has a pedicle should undoubtedly be excluded from the group, and any tumor larger than the size of a pin's head does not come under this head. Another distinctive feature of these nodules is their situation upon the free edge of the cord, at the junction of the middle with the anterior third, and it is laid down that this is the only position in which they grow.—*Medical Press and Circular*.

American Losses in the Philippines.—The losses from all causes in the regular army and the volunteers from July 1, 1900, to June 30 last, totaled 16,924 officers and men in the former and 8191 in the latter. The casualties to the troops in the Philippines since the date of the first arrival, June 30, 1898, to June 30 last were 115 officers and 3378 men killed, and 182 officers and 2646 wounded.

The Healthiest Land in Europe.—An article in the *Statistische Wochenschrift* upon the comparative increase of longevity in the various nations of Europe imagines that Sweden will before long become recognized as the healthiest of European lands. In the early part of the last cen-

tury its sanitary reputation was bad, but between 1830 and 1840 its mortality was reduced to 26.8 in the 1,000. Each successive decade has shown a remarkable improvement in the longevity of its inhabitants. In 1870 the deaths were 20.2 in the 1,000; in 1880, 18.3; in 1890, 16.9, and lastly, in 1900, 16.5. With such favorable conditions of health it is no wonder that the tourist in Sweden should say that he "met an old Swede at every turn."

It is not generally known that a man, to be perfectly well proportioned, should weigh 28 pounds for every foot of his height.

Mosquitoes Blamed Again.—Selence has gone a step farther in incriminating mosquitoes for the propagation of marsh fever. A French army doctor in Algeria has proved that an outbreak in a barrack standing in marshy ground was coincident with the first appearance of the mosquitoes for the season. All cases were first attacks.

Yellow Fever in Mexico.—The Mexican Superior Board of Health learns that yellow fever continues in Vera Cruz and on the Isthmus of Tehuantepec. There have been several new cases at Vera Cruz and on the Isthmus.

International Sanitation.—At the Pan-American Congress just held in the City of Mexico, a plan of international agreement for the sanitation of sea coast cities, particularly against yellow fever, has been suggested by an agent sent by Surgeon General Wyman of the Marine Hospital Service. He proposes sanitary improvements of harbors, improved sewerage, soil drainage and paving, and the elimination of infection from buildings. An international sanitary commission should be appointed, comprising five members, a diplomat, a lawyer, a physician and sanitarian, a sanitary engineer, and a commercial representative. To these five it is proposed to add temporarily two to represent the government in whose domain is located the city or town to be investigated or made to conform to sanitary requirements. The duties of the commission would include visits to the cities and reports upon the sanitary measures necessary. If the president of the State in which the unsanitary city is located fails to carry out the recommendations of the commission within a year, then, under Surgeon General Wyman's plan, all the republics will impose upon vessels arriving from it an additional tonnage tax and duties upon specified imports from the port, until the sanitary work has been completed.

Malaria and Mosquitoes.—Last year an Italian scientific expedition visited Northern Sardinia in order to study malaria. 104 people composed the expedition, and they all covered the exposed part of their bodies with netting. But one of them developed malaria. A thorough and detailed investigation has but recently resulted in the discovery that he had removed his head mask at night, in order to smoke.

An Indian Burying Mound.—E. P. Valentine, of Richmond, Va., has discovered an old Indian burying mound on Hays Creek, in which he unearthed 300 skeletons of men, women, and children. They were found lying in concentric circles in the mound, which was about seventy feet in diameter. Some were in a good state of preservation with the hair yet intact. Some were lying feet to feet, while others were head to head. A skeleton of a dog or wolf was found. In the center of the last or inner circle, which was twenty-four feet in diameter, were found four layers of bodies, each covered by a layer of stone. On the forehead of each skeleton found was a piece of limestone 8 by 10 inches and 2 inches thick. Many of the skeletons were taken to Richmond.

The Glove as an Infecting Medium.—The surgeon cannot be too careful about his gloves. After operating upon septic cases, it is exceedingly difficult to render the hand again aseptic for some time. Hence the advisability of wearing rubber operating gloves in septic cases. The surgeon is very apt to wash his hands with less care after an operation than before, and going from his operating room into the carriage, draws on his driving gloves or outdoor gloves, which, in turn, rapidly become infected with staphylococci, streptococci, etc., so that for days or weeks the surgeon's hands are reinfected by means of his own gloves. This occurred some years ago to an obstetrician in whose practice several cases of puerperal fever arose. After a most careful investigation, giving up his obstetric practice, it was found that his driving gloves had been contaminated by his hands from a case

of scarlet fever he had treated some time previously. The *Pacific Medical Journal* urges the necessity of wearing surgeons' gloves at all operations having pus, and suggests that the surgeon does not wear outdoor gloves for several days after a septic operation, so that the air and sunshine with the natural attrition of the skin will destroy the infection, and not communicate it to the glove, which may in turn reinfest the hands for days and weeks thereafter.

The Idiotic Children of a Cocainomaniac.—Marfan has recently reported the interesting case of a man who had been addicted to the excessive use of cocaine for eight years, from having employed it to relieve hypertrophic rhinitis. He absorbs as much as three grammes by the nose daily. His last two children, boys aged 6 years and 10 months, are both idiots. Marfan believes this condition to be the result of the father's cocaineomania.

Obituary.—Dr. William K. Doherty, San Francisco, Cal., October 9, aged 70 years.—Dr. William L. Harding, at New York City, October 11.—Dr. W. W. Duvall, at Gladstone, Md., October 13, aged 80 years.—Dr. Donald R. Hinekey, at Northampton, Mass., October 14, aged 30 years.—Dr. H. K. Jilison, at New London, Wis., October 15.—Dr. Paul Shultz, Bloomsburg, Pa., October 16, aged 28 years.—Dr. William E. D. Jewson, at New York City, October 15, aged 84 years.—Dr. Samuel J. Jones, at Hyde Park, Ill., October 4, aged 65 years.—Dr. Hannah E. Longshore, at Philadelphia, Pa., October 18, aged 82 years.—Dr. Charles H. Voorhees, at Philadelphia, Pa., October 19.—Dr. Henry R. Rogers, at Dunkirk, N. Y., October 19, aged 79 years.—Dr. Joseph Sanders, at OH City, Pa., October 21 aged 34 years.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended October 19, 1901.

SMALLPOX—United States.

GREAT BRITAIN.

Glasgow University.—Dr. John Young, professor of natural history in the medical department of Glasgow University has been obliged to resign on account of ill health. He has held the position as professor of natural history for thirty-five years. He was also lecturer in geology and curator of the Hunterian Museum.

Vaccination in Schools.—The Council of Almoners of Christ's Hospital, one of the largest boys' schools in London, is having all the boys in the school, who have not been vaccinated or revaccinated within the last seven years, vaccinated now.

An Immense Reservoir.—Rapid progress is being made upon the new reservoirs at Staines, Middlesex, for the supply of London, and it is anticipated that they will be completed in about two years. The reservoirs are approximately four and a half miles in circumference, and their capacity will be 33,000,000,000 gallons—a sufficient supply to serve the district catered for by the water companies to whom they belong for 100 days. The reservoirs will be supplied from the flood water of the Thames.—*Indian Medical Record.*

Metropolitan Medical Schools.—From information received from the deans of some of the metropolitan medical schools, it would appear that the number of medical students taking the full medical course has diminished this year. On the other hand, those wishing to take a special or partial course have greatly increased in number.

A Bequest to the Hospitals in Glasgow.—By the will of the late Sir William Laird, £50,000 was left to the various hospitals of Glasgow and West Scotland.

Harveian Oration.—Dr. Norman Moore delivered the Harveian Oration at the Royal College of Physicians in London, on St. Luke's Day, October 18, 1901.

Appointments.—Dr. Lindsay Steven has been appointed examiner in medicine and clinical medicine, and Dr. Charles Workman examiner in pathology, in the University of Glasgow.

A Martyr to Science.—A tablet to the memory of the late Dr. Walter Myers, of Birmingham, given by the Liverpool School of Tropical Medicine, has been erected in Birmingham University. Dr. Myers died of yellow fever in Brazil, while investigating the pathology and etiology of that disease.

CONTINENTAL EUROPE.

The New Home of the French Academy of Medicine.—As soon as the superb new building on the Rue Bonaparte is finished, the Academy will move its valuable collections, comprising 200,000 volumes, 120,000 manuscripts, and over 6000 portraits and engravings, from the old chapel of the Rue des Saints Pères, where it has been located for fifty-one years. The new building, which contains a large amphitheatre, library, laboratory, vaccinating rooms, etc., cost over \$300,000.

Expansion of American Quackery.—An advertisement appeared in a Russian newspaper offering a sure income of 125 to 250 roubles a month, for the introduction of a patented American remedy. Similar advertisements of various panaceas invented in America appear from time to time in the daily press, and are even distributed in the form of circulars. Is this a sign of overproduction or a general tendency to expansion?

A Great Honor.—The statue of Dr. Armauer Hansen, the discoverer of the bacillus of leprosy, by Visdal, the Norwegian sculptor, was erected in the gardens of the Museum in Bergen, Norway, upon his sixtieth birthday. Professor Lassar delivered an address, in which he remarked that it had taken the world a quarter of a century to fully realize the import of Dr. Hansen's discovery, but that already, in consequence of it, great improvements had been effected in Norway, long one of the favorite haunts of that terrible disease. That this has happened during the life of Dr. Hansen shows the high esteem in which he is held by his countrymen.

The New Children's Hospital in Paris.—The new Trousseau Hospital, in the Rue Michel Bizot, by far the handsomest hospital in Paris, has just been finished at a cost of almost \$400,000. The ground, which includes about 20,000 square meters, contains 21 pavilions, separated by extensive grass-plots. Upon the street next to the main entrance are the home of the director and the dispensary, to which a bath-

ing establishment is attached. The dispensary has a special entrance, and the medical and surgical cases are at once separated, the suspicious contagious cases being placed in a small room, twelve of which adjoin the waiting-room. The medical building contains four large wards of twelve beds each, with a separate small home for infants, with eight cribs and four rooms for mothers with children. The surgical service consists of two buildings, one for septic cases, containing two wards of ten beds each, the other for general surgery, with two wards of sixteen beds, one of twelve beds, a room for four infants, and four rooms with one bed. Each department has its own operating room. There is one pavilion for doubtful, suspicious cases, containing sixteen separated glass box-rooms; very similar to this are the four contagious pavilions, each containing two wards of eight beds, and the diphtheria pavilion, with twelve separated glass rooms and a ward of eight beds for convalescents. Beside these buildings, all of which also contain baths, water-closets, laundries, electric lighting, hot air and ventilating apparatus, there are separate pavilions for the mortuary, with an autopsy room and laboratories, for disinfection, stables, kitchen, residents' house, servants and nurses' quarters, the machinery, etc. The cost of construction was much less than either the Boucicaut or Bretonneau Hospital, previously the most modern of the Paris hospitals. While each of the 244 beds of the Trousseau Hospital cost approximately \$1600, one of those in the Boucicaut Hospital cost \$2400. Unfortunately the predominance of septic cases has caused a re-arrangement of the surgical services, 20 beds being devoted to general surgery, while 50 are needed for the septic cases. In the opinion of Dr. F. Jayle, the enormous distance from the more thickly populated parts of Paris to this new hospital will result in a poor dispensary service. The structure, furniture, appliances, and equipment of this new hospital for children are superb.—*Presse Medicale.*

Paris.—Boxes are soon to be placed upon the lamp posts of the streets of Paris, containing dressings for wounds and an alarm with which to call out the nearest ambulance. One has already been erected.

A Fort Made Hospital.—During the next three months the old fort at Noisy-le-Sec will be transformed into a hospital to contain 350 beds. This hospital will be used for the convalescent patients from the Paris hospitals.

Appointments.—Nancy: Professor Gross has been appointed dean of the medical faculty.—Algiers: Dr. Bruch, professor of clinical surgery, has been appointed director of the medical school.—Marseilles: Dr. Queirel, professor of obstetrics, has been appointed director of the medical school.—Angers: Dr. Raimbault, professor of pharmacy and materia medica, has been retired, becoming honorary professor.—Clermont: Dr. Blatin, professor of physiology, has become honorary professor upon his retirement.—Rennes: Dr. Bellamy, professor of medical chemistry, has become honorary professor upon his retirement.—Rouen: Dr. Tincl, professor of anatomy, has been retired, becoming honorary professor.

Obituary.—Dr. Hans Wiss, professor of medical jurisprudence, is dead.

A Peculiar New Bacillus.—From Vienna comes the news of the discovery of a peculiar bacillus, gas producing, yet only developing where oxygen is excluded. Dr. Gussenbauer, professor of surgery in the University, noticed that, in several operations in which asepsis had been maintained, there occurred "gas abscesses" which prevented recovery. Then bacteriological examination brought to light this peculiar new bacillus. Later it was found upon the ceiling and walls of the operating room.

Typhus Fever in Prussia.—An epidemic of typhus fever has broken out at Gelsenkirchen, Westphalia. Over 2000 persons out of a population of 12,000 are already ill with the disease. From forty to sixty new cases are reported daily. Dr. Koch, who is continuing his investigations there on behalf of the government, says he believes the epidemic is due to the bursting of pipes in a house where a typhus patient was under treatment, this leading to an infection of the entire water system with typhus bacilli.

A Danish Physician Contracts Leprosy.—Dr. Fellberg, City Physician of Copenhagen, who recently visited the West Indies, is suffering from a strongly developed case of anesthetic leprosy, which he is believed to have contracted from a patient whom he attended while in the West Indies. The case is regarded as hopeless.

1.—Byers, as President of the Obstetrical Section of the British Medical Association, gave some introductory remarks on puerperal fever, uterine cancer and the falling birth-rate. He states that in 1847-56 the mortality from puerperal fever in England and Wales was 1.8 per thousand. It rose to 2.28 in 1875-84, and to 2.46 in 1886-95. He believes that by the observation of the two principles—the avoidance of meddlesome interference and the rigid use of antiseptic principles—we may hope that in the present century the occurrence of puerperal fever will eventually be as rare in private practice as it became in the nineteenth century in lying-in hospitals. As regards the falling birth-rate he states, that in England and Wales in 1861-71 the birth-rate per thousand was 34.8; in 1871-81 it was 34.7; in 1891 it was 31.4 per thousand and since then it has steadily gone down until in 1900 it was only 29 per thousand. In other words the birth-rate has fallen by 2.67 in the last ten years. He remarks that if fewer children are in the future to be born in England the efforts to lower the high death-rate of infants must be doubled. [W. A. N. D.]

2.—In a discussion on the causation, prevention, and treatment of miscarriage, Horrocks remarks that the proportion of miscarriages to labor at term has been estimated differently by different authors. According to the reports of the Guy's Lying-in Charity the proportion in 25,777 cases was about 1 to 182. In fact the proportion is far greater than this, when all the instances of miscarriage are included. Some authors give the proportion of 1 to 5, and probably that underestimates it if anything. A primipara is less likely to miscarry than a woman who has already had one or more children. The majority of early miscarriages are criminal. Anything that disturbs the attachment between the fetus and the mother may cause miscarriage, such as overstraining, hard work, coughing vomiting, etc. Surgical operations, major or

minor, may likewise induce abortion. The extraction of teeth is peculiarly liable to cause miscarriage, probably because of the increase in the intraabdominal pressure, as the patient holds herself to bear the pain, or possibly owing to the influence of shock. Fibroid tumors are very apt to induce a miscarriage, as are also diseases of the adnexa. Syphilis is the most potent and probably the commonest of fetal causes. Endometritis is supposed by some to play an important rôle in the production of miscarriage. Displacements of the uterus, especially retroflexion, zymotic diseases, eclampsia, placenta previa, cancer of the cervix, over-suckling and traumatism are all to be grouped among the causes of miscarriage. As to the prevention of this accident nothing must be done by the patient, that would be likely to disturb the connection between placenta and uterine wall, damage to the ovum, or rupture of the membranes. Hence she must avoid riding, dancing, golfing, tennis, cycling, excessive coitus, lifting, walking, or standing too long, and all shocks and frights. Tight lacing should be avoided, the bowels should be kept open but without purgation; enemata must be given with caution; if syphilis is suspected antisyphilitic treatment is indicated. Hawkins-Ambler thought that recurring miscarriage is due to endometritis oftener than is believed. As regards the treatment of miscarriage, the finger is undoubtedly the best means of emptying the uterus. Lycett said that the erect carriage of the woman with the consequent frequent association of uterine displacement has not *per se* any direct influence in producing miscarriage. He believes in the toxic influence which alcohol undoubtedly has in the production of premature discharge of the ovum. Duncan regards retroflexion as a common cause and advises the use of a well fitting pessary. Parsons believes that healthy subjects may do almost anything without abortion occurring, but when the woman is delicate or when abortion has already previously occurred unusual precautions must be taken. [W. A. N. D.]

3.—Horrocks reports a case of deciduoma malignum occurring in a patient aged 48, who had had two miscarriages prior to the appearance of the disease. The uterus was removed and showed the characteristic features of the disease. The patient subsequently succumbed to a recurrence, but no postmortem was allowed. [W. A. N. D.]

4.—Kerr reports three cases of Cesarean section which he has met with in his own practice, the operation being indicated by extreme degrees of pelvic deformity. He remarks that in cases of pelvic deformity we are now hardly ever justified in destroying a living child by craniotomy or any other destructive operation. The only circumstances under which such operations are permissible are where fruitless attempts have been made to extract the child by forceps or inversion from ignorance of or miscalculation of the extent of the pelvic deformity, where the mother's condition is such as to preclude abdominal section, and where the child is the subject of hydrocephalus or some other extreme malformation. The only advantage of the fundal incision in Cesarean section, as far as Kerr can see, is that the wound is removed from the most probable source of infection. [W. A. N. D.]

5.—Hawkins-Ambler discusses shock in abdominal operations. He remarks that operative interference in a healthy animal is followed by a certain degree of apoplasia or drying of the blood. This depends to some extent on the severity of the lesion, but it is always considerable. It causes an increase in the specific gravity of the blood. This is also in association with a change in the condition of the nerve-cells. There occurs a decrease in the size of the nucleus, an irregularity in its outline, and it takes a darker stain. There is also a slight shrinkage in the size, with vacuolation of the cells in the spinal ganglia. Time is an important element in the production of shock. Add to this the hemorrhage of the operation, the direct loss of blood from severed vessels, and the exudation of plasma which is a constant factor, and it is easily realized that the effect on the circulation may be enormous, and that heart and brain may be dangerously deprived of blood in these directions. The author advocates prophylaxis. A visit to the country prior to the operation is an excellent thing in its way and improves the chances. He states also that patients are sometimes starved and purged too much before operation. At times it may be of value to eliminate the shock of general anesthesia; in a warm room and on a hot-water table the chances of shock are diminished. Saline injections by the rectum or hypodermically are of the

utmost value in the treatment of the developed condition. Small doses of morphin with atrophin given hypodermically before the patient leaves the table prevent the development of the condition. [W. A. N. D.]

6.—Duncan states that there are four conditions indicating operation upon uterine fibroids, namely: (1) when they cause severe hemorrhage; (2) when they cause pressure symptoms; (3) when they are growing rapidly larger; (4) when they complicate pregnancy. The removal of the appendages, either to stop hemorrhage or arrest the growth of the tumor has now been dropped, because of failure to obtain the desired results. Hysterectomy is the best operation to perform in most cases of uterine fibroid which require medical treatment. It is performed in various ways. Panhysterectomy is the name given to the removal of the whole uterus, either through the vagina or after opening the abdomen. Intraperitoneal hysterectomy is one of the terms used when most of the uterus is removed, leaving a stump consisting of a portion of the cervix. When a fibroid tumor takes on rapid growth, this is due to cystic or mucoid degeneration and always calls for hysterectomy without delay. When pregnancy occurs in a uterus, the lower portion of which is occupied by fibroids obstructing the pelvic brim and perhaps filling the pelvic cavity, three courses are open, namely: (1) To empty the uterus; (2) To at once perform hysterectomy; (3) to permit the case to go to term and then to perform Cesarean section followed by hysterectomy. [W. A. N. D.]

7.—Lockyer reports a case of *cystic fibromyomata* in a single woman, aged 22 years, which was discussed by Doran. He states that small, hard fibroids which cause no pressure-symptoms and are not associated with hemorrhage, should not be removed, but fibroids which are increasing and softening or which press on the bladder, rectum or important blood-vessels, or which cause continuous metrorrhagia should be removed. Doran has operated on 29 bad cases of fibroid of the uterus since January 1, 1901. In every case the operation was retroperitoneal hysterectomy. Martin does not advocate operation as routine treatment. Each case must be considered on its own merits. No operation should be done if the tumor is stationary in size, if the hemorrhage be moderate and controlled by rest and ergot, or if the patient be near the menopause. The operations that may be performed are vaginal myomectomy, vaginal hysterectomy, abdominal myomectomy, and panhysterectomy; the latter he regards as the best and safest operation for the majority of cases of big myomata demanding operation. Cousins states that the tendency of the discussion shows that fibroid tumors, with very few exceptions, should be removed by the abdominal route and not by posterior vaginal operations. [W. A. N. D.]

8.—Jayle describes a new gynecological position which consists in the combination of the ordinary position of the speculum or of the lithotomy position, and of the sacral dorsal position of Trendelenberg. In order to obtain this position it is necessary to have a balancing table with a system of shoulder-rests which hold the patient in a delicate position without securing the lower members, which remain free. This position can be used either for examination or operation. It has the advantage of throwing back the intestines, of determining by the entrance of air dilatation of the vagina which becomes almost vertical, and finally of stretching the anterior vaginal wall. As a result exploration of the tubes and ovaries and especially of the uterus is greatly facilitated. The introduction of the speculum is very easy, and exploration of the vaginal walls is easy, for it is sufficient to depress the perineum either with the finger or with the valve speculum in order to get a good view of the anterior wall and at times of the cervix. [W. A. N. D.]

9.—Smith records a successful laparotomy for abdominal pregnancy with removal of a full term fetus, placenta, and gestation-sac *en masse*. The patient was a woman, 26 years of age; the fetus a well developed female, weighing 10½ pounds and measuring 20 inches. He states that tubo-abdominal, tubo-ligamentary, subperitoneal, and tubo-ovarian pregnancy may go on to term. He believes the present case was primarily a tubal pregnancy which had ruptured into the peritoneal cavity. The fetus was dead, but he was unable to say how long. No movements had been felt for three months but there was no evidence of maceration, peeling, or skeletization. [W. A. N. D.]

10.—Boyd describes a case of twin pregnancy, extrauterine

and intrauterine. The tubal ovum in this case perished in a very early stage in the third or fourth week, while the intrauterine pregnancy continued to term. [W. A. N. D.]

11.—Gilford discusses ovarian pregnancy and remarks that the first instance on record of impregnation of an ovum within a Graafian follicle is probably that which is mentioned by Bernutz and Goupil. Granville in 1820 recorded another. During the latter half of the nineteenth century other cases were recorded, but Tait and other authorities believed that true ovarian pregnancy was exceedingly rare, while Bland-Sutton expressed his belief that it was impossible. It is now known, however, that such a condition can exist. Gilford describes the cases that are now recognized as authentic cases of ovarian pregnancy. [W. A. N. D.]

12.—In a discussion on the diagnosis and treatment of metritis and its relationship to malignant disease, Campbell remarks that early pregnancy may be mistaken for this condition, especially when the metritis has produced considerable enlargement and congestion. The character of the discharge in metritis may present a superficial resemblance to cancer, and the appearance of the cervix may also temporarily deceive the observer. The mucopurulent and viscid discharge of metritis contrasts with the red, serous, and foul smelling flux of cancer. Incomplete abortion may simulate metritis and can only be distinguished with certainty from it by curetting and discovering thus the characteristic placental tissue. Fibroids, salpingitis, cystitis and proctitis may all simulate the disease. As regards the treatment of metritis, prophylaxis is most important, and this includes the careful attention to patients in labor and abortion. An abdominal belt, the use of douches and hip-baths, the use of the tampon in suitable cases and daily applied, local bleeding, intrauterine medication and curetting are all included in the cure of this condition. Curetting is admittedly the best of all the methods and should be done under thorough vaginal and uterine antisepsis. Two varieties of metritis are worthy of especial attention as regards treatment, namely, the hemorrhagic and the chronic painful metritis; for the former hot douches, the recumbent posture and the administration of ergot are unquestionably useful. In bad cases tamponade of the uterus may be required. Chronic painful metritis is one of the most troublesome forms of the complaint. In it a certain amount of benefit will be derived from scarification and puncture. The virtues of ichthyol are, he thinks, very doubtful. Columnization of the vagina may have a good effect. The relationship between metritis and cancer of the cervix has not so far been demonstrated beyond question, but the evidence in favor of its existence is strong. The connection between metritis and cancer of the body of the uterus has been definitely settled. [W. A. N. D.]

Scharlieb also discusses the relation of metritis and endometritis to malignant disease of the body of the uterus. She states that the endometritis appears in various forms such as the glandular, interstitial, hypertrophic, exfoliated, gonorrheal, tuberculous, and septic. The first four are named from their histological characters, and the last three from their microbial causes. She quotes various authorities who speak of the relationship between adenoma and metritis and endometritis. Snow in discussion states that in these cases the patient should never be condemned to hysterectomy on microscopic evidence alone. That instrument should only be employed to conform an opinion based already on other grounds. Lawrence recognizes the difficulty of diagnosing metritis as a pure and simple condition independent of disease of the tubes. He advocates full dilatation of the cervix and exploring by the finger before using the curette. Parsons states that certain cases of metritis are chronic in spite of all treatment, and that metritis is probably an antecedent condition in all cases of cancer. Handfield-Jones considers that the treatment of endometritis depends on the degree and virulence of the infection, whether gonorrheal or syphilitic. [W. A. N. D.]

13.—Parsons gives a further report of his new operation for prolapsus uteri. He states that four years have now passed since the first patient was treated by this method, and he has now the record of forty operations. The operation does not prevent or interfere with pregnancy. The general idea of the operation is to strengthen the band within the broad ligaments and enable them to hold the uterus. This band, consisting of fibromuscular and elas-

the tissue, runs upward and outward to the walls of the pelvis. This strengthening is secured by the use of a stimulus, which is antiseptic and has a local action. Sulphate of quinine fulfills these conditions, and this is the substance Parsons injects into the broad ligaments through the vagina. One injection is not always sufficient and after the injection has been made, a pessary should be used to give support until the drug has exerted its action. [W. A. N. D.]

14.—Martin describes a case of **extirpation of the uterus and vagina for intractable prolapse**. This operation is indicated in cases in which the pessary cannot be maintained or where the patient objects to its use, or where the ordinary suspending operations have failed. [W. A. N. D.]

15.—Haultain reports a successful case of **abdominal hysterotomy performed for chronic uterine inversion**. The abdominal route presents three distinct advantages over the vaginal as recommended by Küstner and Piccoli: (1) the uterine incision is reduced to a minimum; (2) the assistance acquired by being able to pull on the broad and round ligaments as well as by pushing up the fundus; (3) the more efficient control of hemorrhage which can be acquired by stitching the incision in the uterus with the organ in its normal position, and not in an exaggerated state of ante flexion or retro flexion. [W. A. N. D.]

16.—Itolleston finds that a previous attack of **enteric fever** in England, India, Egypt, or even in South Africa itself does not necessarily protect the individual against enteric in South Africa. He believes that the explanation of this condition lies in the assumption, that there are varieties in typhoid infection, just as there are in streptococcus infection, only in a less marked degree, which do not mutually protect against each other. It follows that atypical cases of enteric fever should be more often followed by relapses than the typical straightforward cases. He has found that antityphoid inoculation does not absolutely protect against a future attack of enteric fever; but when enteric does occur in an inoculated person there is, as a rule, an interval of at least 6 months before the appearance of the disease. He believes that inoculation protects against a fatal termination of the disease. The explanation of the occurrence of enteric fever after inoculation is much the same as that of the occurrence of a relapse or of a second attack of that disease, and may be briefly summarized by supposing that the individual has been rendered immune against some, but not against all the strains of the typhoid bacillus. Among 244 cases there were 52 relapses, or 21%. In a certain number of cases already in the hospital for dysentery, enteric fever developed. In many of these it appeared that dysentery and enteric fever had been contracted at the same time, and that the comparatively long incubation period of enteric fever accounts for the fact that the enteric fever appeared a considerable time after the dysentery. It is probable that when a mixed infection of saprophytic germs and typhoid bacilli attacks the alimentary canal, the diarrhea which rapidly results may so thoroughly remove the typhoid bacilli that the disease does not develop, and that for the time being, at least, a certain degree of immunity to typhoid fever may result. A noticeable feature in many cases was the rapid pulse rate during convalescence, becoming more manifest when the patient was first allowed to get up. This rapidity of pulse was connected with the continued hard work involved in "trekking" previous to the onset of the attack. Considerable hemorrhage from the bowels occurred in 21 out of 244 cases, or 8.7%. Of these 21 cases 76% were fatal. Phlebitis was the commonest sequel and its usual situations were the deep veins of the leg and the femoral vein. There were 3 cases of enteric fever in which the testes were inflamed. There was one case of solitary abscess of the liver and one of multiple abscesses of the skin about the buttocks. [J. M. S.]

17.—Ross and Reynolds saw cases of **arsenical poisoning** at Chester, England, that were so similar to cases of **beriberi**, seen in the East, that the idea that some beriberi cases might have an arsenical origin suggested itself. In August, 1901, at Sierra Leone, a lady was seen who was suffering from a **peripheral neuritis** so similar to beriberi and to arsenical neuritis that the diagnosis was reserved. The patient, who was 27 years old, was the wife of a missionary. She went to the West Coast of Africa in November, 1900, and lived

largely on canned foods, especially fruits of American origin. She was a total abstainer from alcohol. She had a feverish attack in May, 1901, which was described as "low fever." Shortly after this there was pricking at the ends of the fingers and the legs became so weak that she felt unsafe when walking. At this time the patient was pregnant and at the same time the forearms and arms became weak and wasted. There was no actual pain but there was total loss of power in the legs and in the arms and hands, which was of gradual development, as well as well-marked edema of the feet, legs and hands. In July she was delivered of a dead child at full term and the paralytic symptoms then became worse. She started for England and at once began to improve. During the voyage a marked erythema developed on various parts of the body. After treatment with solution of strychnine there was gradual improvement. A lock of the patient's hair was found to contain a considerable quantity of arsenic. [J. M. S.]

LANCET.

October 5, 1901.

1. A Case of Acromegaly. J. PIRIE.
2. Morvan's Disease (?) or Leprosy. D. DOUGLASS CRAWFORD.
3. An Interesting Case of Compression. EUGENE J. O'MEARA.
4. A Case of Sudden Death Eight Days After Amputation of the Forearm. P. N. GERHARD.
5. Physiological Phenomena preceding or accompanying Menstruation, etc. HELEN MACMURCHY.

1.—Pirie reports a case of **acromegaly** which occurred in a married woman 43 years of age. The disease first showed itself in 1886, at which time menstruation suddenly ceased and there developed paresthesia, pains in the arms and legs, headache, and dimness of vision in the left eye, enlargements of the hands and feet, and alteration in the contour of her face. Twelve months after the onset of the affection she gave birth to her last child. In the course of the disease she developed glycosuria, which condition, however, abated during the last few years of her illness. In September of 1896, she presented the classical features of acromegaly. The lymphatic glands were enlarged, and in the sites of the parotid and submaxillary glands there appeared large swellings; goitre also developed. The enlargement of the hands was limited to an increase in the breadth rather than an increase in the length. The patient also suffered from tachycardia, profuse perspiration and seborrhea, particularly well marked about the scalp. The patient's voice was hoarse, the appetite was large, constipation was a symptom, and attacks of bilious vomiting occurred. Many of the muscles of the extremities and the scapular muscles wasted, but this change did not affect the muscles of the trunk. Slight exophthalmos was present. A coal tar product was administered for the relief of pain with considerable success. Typhoid gland substance appeared to give a limited improvement. The patient died suddenly. A post-mortem examination was refused. [F. J. K.]

2.—Douglas-Crawford reports a case of **Morvan's disease (?) or leprosy**. This condition occurred in a man, 27 years of age, who had been employed in a lime quarry for five years. He was compelled to give up this occupation on account of the development of fissures in the palms of the hands. These persisted even after a change of employment. Six months after the change of occupation, he again returned to his former work in the lime quarry. He continued at his work intermittently until November 6, 1899. Whitlows unaccompanied by pain began to form on the fingers of both hands. A few years before he came under the observation of the author, a swelling of the right shoulder and subsequently of the arm developed, which afterward left the shoulder joint greatly enlarged. Fluctuation was detected in the joint. Fluid was withdrawn from the joint five times by incision; at each time the oper-

ation was followed by great relief to the patient, but the condition rapidly returned. The digits of both hands were swollen and deformed, speech was indistinct. He could not protrude the tongue or move it laterally. The skin covering the fingers presented impaired sensation to pain, heat, and cold. The knee-jerks were exaggerated and the plantar reflex and ankle clonus were well marked. The upper thirds of both thighs and the dorsal surface of the feet also showed impaired sensation to pain, heat and cold. A slight plastic condition of the gait was noticed. After a year (ending in July, 1901) the disease presented no signs of advance. [F. J. K.]

3. O'Meara reports an interesting case of compression which developed in a man 26 years of age, after an injury inflicted to the head with a heavy stick. The signs of compression showed themselves in about 24 hours after the injury. The patient was operated upon under slight chloroform anesthesia; the trephine was applied over the anterior branch of the right middle meningeal artery. On removing the bone, a clot protruded through the trephined hole, but the artery was uninjured. Another opening into the skull was made over the posterior branch of the middle meningeal artery, but again the seat of hemorrhage could not be determined and this artery was uninjured. A large clot was removed with a spoon—the brain expanding as the clot was turned out. Strips of gauze were introduced between the dura mater and the bone in order to assist in draining the hemorrhage and to minimize as far as possible the danger of edema from too sudden expansion of the brain. The hemorrhage continued for 36 hours after operation and in 48 hours after it ceased; the gauze was then carefully removed and the flaps drawn over the opening and stitched together with wire sutures. The patient made a gradual recovery without the development of any cortical irritation or mental impairment. [F. J. K.]

4.—P. M. Gerrard reports a case of sudden death occurring eight days after amputation of the forearm. The patient was up and walking about when he was suddenly taken ill and died within a very short time. The postmortem showed a clot situated in the right auricle extending into the ventricle and it is this that Gerrard believes produced the death. No pulmonary embolus was found. The case was a septic one. [J. H. G.]

MEDICAL RECORD.

October 19, 1901.

1. The Case of President McKinley.
2. Failure of the Knife in the Treatment of Cancer.
ROBERT REYBURN.
3. Report of the Summer Work of the Milk Commission of the Medical Society of the County of New York.
HENRY DWIGHT CHAPIN.
4. Laboratory Aid in Surgical Technique.
GEORGE B. BROAD.

1.—See the Philadelphia Medical Journal, October 19th issue, 1901.

2.—Robert Reyburn discusses the failure of the knife in the treatment of cancer. After prolonged study of the subject, this writer has come to the conclusion that when an incision is made into any part of the body for the removal of a malignant growth, we at once divide and lay wide open for infection every vein and lymphatic vessel in the part operated upon. No matter what we may believe to be the contagium of cancer, the fact remains the same. Reyburn believes that the operative measures may be substituted by the electric cauter, or, in a limited number of cases, the use of arsenic or chloride of zinc for the removal of morbid growths. He concludes that the results of John Byrne in the treatment of uterine cancer show that the treatment of this affection by the electric cauter will accomplish the best results. [T. L. C.]

3.—Henry Dwight Chapin, of New York, Chairman of the Milk Commission, appointed by the Medical Society of the

County of New York, reports upon the summer work of the commission. The commission have considered: 1. The condition of the barns. 2. The condition of cows. 3. The milkers. 4. The condition of utensils. 5. The process of cooling. 6. Transportation. 7. Condition of cans or bottles when returned from the city. Considerable amount of data is included in this article as a result of a summer study of the milk question. The information is the result of thirty visits made to various farms and dairies, some at a distance of 100 miles. Each of these visits consumed, at least, one day, and some several days, so that a thorough study of the matter could be made. In general, they suggest that the essential conditions for thorough sanitary preparation of milk may be included under three heads: First, strict cleanliness, which includes the barns, yards, cows, milkers, and all utensils. Bacteria which get into the milk by means of dirt are thus thoroughly excluded. Second, rapid and sufficient cooling of the milk. The few bacteria that do get in are thus prevented from growing. Third, thorough icing around the milk until it reaches the consumer. The production of toxins from the growth of bacteria is thus retarded. [T. L. C.]

4.—George B. Broad presents a paper on laboratory aid in surgical technique. He describes the difficulty of disinfecting the hands and the failure of blechloride of mercury and formalin to accomplish this end successfully. The possibility of the suture material being contaminated and the methods for its sterilization are also discussed, as well as the sterilization of rubber gloves and the gauze to be employed. [T. L. C.]

P. M. RIXEY, MATTHEW D. MANN, et al.
6. Report of the Summer Work of the Milk Commission of the Medical Society of the County of New York.
HENRY DWIGHT CHAPIN.

1.—J. A. Wyeth reports a case of operative pre-peritoneal rupture of the bladder, and says that he has performed between 60 and 70 suprapubic cystotomies and in every case sterile water was injected, the minimum quantity varying from twelve to fourteen ounces, and, in bladders which have been distended by retention, at times twenty-four ounces have been employed. In no other case than this now reported has rupture occurred. He has advised the injection of as much fluid as can be safely carried, in order to give the operator as much room as possible between the vesical peritoneum and the symphysis pubis. In cases where the habit of frequent micturition has prevailed through several years, leaving the bladder in a more or less contracted condition, it would be advisable to contend with the difficulties and possible dangers of operating through a narrower incision, with from eight to ten ounces of injected liquid, rather than run even the very small risk of rupture of this organ by employing the greater quantity. [F. M. T.]

3.—C. R. Greenleaf concludes his article by saying that

no tropical islands in the world enjoy a better climate than do the Philippines; but certain classes of diseases have to be reckoned with there. As to the disease, if proper laws are enacted or enforced to govern the public health, the intelligent foreign visitor or resident may enjoy almost perfect immunity from sickness, provided he will only take care of himself. The native, however, does not know how to take care of himself; not only is he ignorant of the first principles which govern the preservation of health, but he has never had anybody sufficiently interested in him to instruct him in these principles. It has been part of the duty of the Philippine Commission to so instruct him. [T. M. T.]

4.—E. B. Dench states that early operative interference in Acute Mastoiditis is advisable, as it should be remembered that under aseptic precautions, the opening of the mastoid process is without danger. On the other hand, delay in a doubtful case may lead to most serious complications, such as infection of the intracranial structures. [T. M. T.]

6. Association of Anemia with Chronic Enlargement of the Spleen. (Continued).

ARTHUR H. WENTWORTH.

1.—Thorndike reports the following cases: (1) A case of renal calculus composed of uric acid and urates, in which there was abundant clinical indication for operation without the confirmatory evidence of an indistinct shadow on the X-ray plate, which shadow was, however, undeniably present. (2) A case of hydronephrosis in which stone was suspected, and in which a most complete exploration of the kidney definitely demonstrated its absence. (3) A case in which there were 3 small calculi of calcium oxalate, probably secondary to a pyelitis, which resulted from the extension upward of an old gonorrheal cystitis, and in which the photographer interpreted a shadow that the writer could not see. In this case also there was ample clinical indication for operation without the X-ray photograph. (4) A case in which a number of uric acid stones, covered with a thin coating of calcium phosphate, in a thoroughly disorganized kidney, could be readily seen, both in the plate and in the print, by the most uneducated observer. In all these cases renal stones were believed to be present, and X-ray photographs were taken for confirmatory evidence. In 3 of them the stones were found, and the fourth case proved to be one of hydronephrosis, due probably to sagging of the kidney. The writer referred to the method of operation by which the entire kidney is lifted on to the loin, and then split along its convex border in such a way as to expose its whole interior to examination. He has been able to carry out this exploratory technique in 6 instances, and has never had the least trouble from hemorrhage or otherwise, either during or subsequent to the operation. In some stout people it is a practical impossibility to carry out this method of investigation, and efforts to do so should not be persisted in. [J. M. S.]

2.—Carcinoma of the tonsil is rare; but when it does occur it is of much gravity, and demands on the part of the surgeon the exercise of a considerable degree of judgment and skill. As a rule carcinoma occurs at a later period in life than sarcoma, and at a time when the lymphatic structures of the tonsil have undergone certain retrograde changes, but the epithelial structure persists. If, as a result of local irritation, heredity, or some unknown cause, nutritive activity undergoes an abnormal increase, we have the conditions which may prove the starting point of carcinoma. It would be expected then that the form would be epithelioma, and it is found, in the great majority of cases, that this is true. If, then, a case of malig-

nant disease of the tonsil comes before one, the diagnosis lies between a round-celled sarcoma and epithelioma. So far as symptoms are due to the presence of a tumor in the fauces, carcinoma resembles sarcoma, but pain is likely to be an earlier and more troublesome symptom with carcinoma. One must differentiate between simple hypertrophy, syphilitic manifestations, tuberculous process, and even phlegmon. The author cited a case that illustrated the difficulties in differentiating between sarcoma and simple hypertrophy of the tonsil. The prognosis of malignant disease is most serious. The tumor should be enucleated with the finger and blunt instruments, if the case is seen before the surrounding structures are invaded; and the cervical lymphatics should also be removed if they are involved. If the new growth has passed beyond the stage that admits of this shelling-out process with reasonable hope of successful issue, external operation is to be performed. [J. M. S.]

1. The Treatment of Malignant Disease. FREDERICK S. DENNIS.
2. Carcinoma of the Cecum, Etc. WM. J. MAYO.
3. On the Growth of the Epithelium. LEO LOEB.
5. Some Considerations Regarding the Hygiene of Early School Life. JULIUS NOER.

1.—Frederick S. Dennis discusses in detail the treatment of malignant disease after first collecting various statistics to show the great increase in cancer during late years. It is shown that in the city of Philadelphia there has been an increase of 179% in the mortality of cancer of the breast when the figures of the five years between 1861 and 1865 are compared with those of 1896 and 1900. The increase however, from the period of 1876 to 1880 to the period from 1896 to 1900, was only 12 per cent. The explanation of this falling off in the death rate during the last few years is attributable to the operative treatment of cancer in this city during that time. In the United States in 1890 there were over 18,000 deaths from carcinoma. The Röntgen rays as a method of treatment of malignant disease are still *sub judice*. Some benefit has certainly followed their use in certain cases of epithelioma, but much more time must elapse before this means of treatment becomes a recognized therapeutic agent for carcinoma. Dennis condemns electricity as "worse than useless." Caustics, although useful in some forms of myxoma have won no stable place in the treatment of cancer. The application of caustics is much more painful than the more radical removal with the knife. With the use of nitrous oxide gas Dennis has been able to operate upon many cases in which the use of ether was contraindicated, and in which formerly caustics might have been recommended. Many drugs, such as formalin, pyoktanin, chian turpentine, methylene blue, potassium iodide, and thyroid extract have at various times been extolled as curative remedies. None of them have, however, done more than alleviate and improve certain cases. No absolute cures have been attributed to any drug. Dennis has obtained more benefit from the use of thyroid extract than from any of the others. Considerable space is devoted to the discussion of Coley's toxin treatment. The author thinks that the only cases in which this treatment is apt to prove of much value are those in which after one or two operations it is used as a prophylactic. It is believed that the knife offers the only absolute cure for cancer. The latter part of the paper is devoted to a discussion of the results which the author has been able to obtain by early and thorough operation. No case is given as a cure which has not passed the three year limit. In every instance the diagnosis of malignancy has been confirmed by the microscope. He presents 87 cases of malignant tumors in which operative treatment has resulted in recovery without recurrence after periods

ranging from three to 22 years. Forty-eight of these were cases of sarcoma, 39 of carcinoma. [J. H. G.]

2.—Wm. J. Mayo discusses the question of carcinoma of the cecum and reports two cases in which the cecum was removed for malignant disease. Ewald has collected 1148 cases of intestinal cancer, and in 61 instances the disease was situated in the cecum and in 26 in the ileum. Lymphatic infection is found in less than one-half the cases dying from intestinal carcinoma. The malignant growth usually originates at the ileo-cecal junction and has a tendency to produce obstruction. The symptoms of the disease are colicky pains, constipation alternating with diarrhea, and progressive wasting. Sometimes the tumor may be felt. It is very difficult to make a differential diagnosis between malignant disease of the cecum and a chronic appendicitis. Occasionally the symptoms come on suddenly, being ushered in by an attack of acute obstruction of the bowels and in other instances by an acute intussusception. Both tuberculosis and syphilis may produce inflammatory thickening of the cecum which will render diagnosis difficult. Mayo recommends the formation of an anastomosis between the end of the ileum and the side of the colon above the seat of disease and then the extirpation of the cecum. If it is found difficult to approximate the cut end of the cecum and the side of the colon, then a side-to-side anastomosis between the ileum and the transverse colon may be made. Mayo has excised the cecum four times, twice for malignant disease, once for tuberculosis, and once for chronic intussusception. All of the patients recovered from the operation. His first case of carcinoma of the cecum was operated upon in April, 1899, and is now pursuing his avocation. In this case a diagnosis of chronic appendicitis had been made. The second case was operated upon in January, 1901, for carcinoma of the cecum. In this case also the condition was believed to be one of chronic appendicitis. [J. H. G.]

3.—Loeb gives the results of investigations which were undertaken to determine the growth of epithelium. In a previous report published in 1898 the *Archiv f. Entwicklungsmechanik*, he showed that epithelium has the power of branching in the coagulated blood of healing wounds. The results of his present investigations show that when epithelium penetrates into the blood of healing wounds, it surrounds small particles of blood and occasionally these epithelial cells present mitotic figures. The blood corpuscles surrounded by a sheath of epithelium did not cause the epithelial cells to become pigmented. He was able to demonstrate that epithelium removed from the body of an animal possesses the power to regenerate cells where placed into agar, and that these cells may invade the agar in all directions. He also observed that some of the cells surrounded particles of agar. In a few instances, the beginning formation of epithelial pearls was observed in agar. He concludes the following: "During its growth the epithelium forms a mass of cells, all layers of which are equally able to grow in different directions. A distinct differentiation between different rows of these cell masses does not exist. Later on the epithelium, which comes into contact with connective tissue well supplied with blood vessels, forms again regular epithelium, the lowest rows producing new cells, which now undergo the changes leading to the formation of normal keratohyalin and keratin. We see that these growing cell masses do not need connections with either resting or growing connective tissue; although under the usual conditions found during the growth of epithelium, the epithelial cells are found accompanied by connective tissue. The possibility of separating the growing epithelium from other tissues might be used to subject an isolated tissue like epithelium to certain experimental conditions, as for instance, to the influence of different chemical substances and thus study the reaction of isolated tissues, other than connective tissue and leukocytes to different stimuli." [F. J. K.]

4.—Noer discusses some considerations regarding the hygiene of early school life. The author states that from

the data at our disposal it is evident (1), that mental and physical abnormalities exist in school children and, (2), that these abnormalities are always aggravated, if indeed they are not actually produced by pedantic, pseudo-educational methods." He emphasizes the following: "Regular periodic medical inspection, which should include physiologic and anthropometric examination of the school children, should be a requirement in all public schools. These examinations would not only furnish valuable physiologic and anthropometric data, but would disclose cases of infectious and other communicable diseases. They would also detect mental and physical defects—stigmata—not readily recognized by parents and teachers. These children with marked mental and physical abnormalities, developmental defects, or stigma, should be segregated for special training. Every town with a school population of from 800 to 1000 will have a sufficient number of children of this sort to fill a room, which should be in charge of a person having the exceptional qualifications necessary for success in this kind of work." [F. J. K.]

AMERICAN MEDICINE.

October 19, 1901.

5. Purpura Hemorrhagica Following Acute Lobar Pneumonia, Recovery. H. L. UNDERWOOD.
6. A New Operating, Dressing and Examining Table. M. G. BURGESS.

1.—See Philadelphia Medical Journal of October 19.

2.—G. R. Fowler reports three cases in which he employed simultaneously spinal cocainization and ether or chloroform narcosis. He believes that this method of inducing anesthesia is of especial advantage in that the nervous dread and anxiety are removed, and at the same time general narcosis is accomplished to the extent of rendering the patient oblivious to the surroundings with a very small dose of the general anesthetic agent. [T. L. C.]

3.—Thomas R. Brown presents a paper on the practical value of blood examination in medicine and surgery. He regards the value of leukocyte count in surgery as established, especially in appendicitis, and for the following reasons: Its presence or absence tells whether we are dealing with an inflammation of the appendix, or with a case of hysteria, floating kidney with twisted ureter, gallstones of renal calculus or the gastro-intestinal type of influenza, these conditions not being associated with a leukocytosis; the grade of the leukocytosis tells us about the severity of the infection; a systematic counting will show whether the condition is becoming better or worse; it may be our only means of diagnosis in a fulminating case, especially in children, in whom many of the characteristic symptoms are absent. [T. L. C.]

4.—Davis records a case of extrauterine primary abdominal pregnancy at full term in a woman, 32 years of age. She was operated on through the vagina, the skull of the child being opened and the entire body removed by morcellation. The patient was slightly septic after the operation, but eventually made a good recovery with the exception of a small fecal fistula, which eventually disappeared. [T. L. C.]

6.—M. G. Burgess describes the new operating, dressing and examining table of elaborate type. Eight cuts accompany the article upon the various positions in which the table may be placed. [T. L. C.]

8. A Case of Cervical and Bulbar Tabes with Necropsy. SOLOMON S. COHEN and WILLIAM G. SPILLER.
9. Some Observations on Typhoid Fever Complicated by Croupous Pneumonia, with Reports of Four Fatal Cases. HENRY M. FISHER.

1.—Finney, discussing the preferable anesthetic to be employed in heart disease, calls attention particularly to the very marked differences observed according to the skill of the anesthetizer. In one case, a middle-aged man, who was subjected to six anesthetizations, showed a variation in the quantity of ether required, from 300 to 1,000 grms. He believes that in cardiac disease remarkably few cases ever exhibit bad symptoms as the result of the administration of ether, and that many of them take chloroform without the slightest symptom that would give rise to anxiety, from the beginning to the end of the operation. Theoretically, chloroform should be considerably more dangerous in cases where there is degeneration of the heart muscle. He gives some statistics, collected from the wards of the Johns Hopkins Hospital, which are based upon 142 cases of various forms of organic and functional disease of the heart. In 8 cases of myocarditis, 5 took ether badly and 3 well. In one of these the initial anesthetization was done with chloroform, but on account of alarming symptoms it was necessary to substitute ether. In one of these five cases the patient died shortly after the operation, but as it was a case of perforative peritonitis, shock was probably the cause of the death. In 7 cases of aortic insufficiency, 4 stood ether well and 3 cocaine. In 6 cases of mitral stenosis, 4 took ether well and 1 chloroform. Local anesthesia was also employed in 2 cases. In 2 cases of aortic stenosis both took ether well in long severe operations. In 49 cases of mitral insufficiency 28 were given ether, 28 of which took it well, 5 rather poorly and 5 badly. Nine cases were operated upon under local cocaine anesthesia and all did well. Two cases were given chloroform. In 7 cases of simple hypertrophy, 5 took ether well and 1 took it badly on 2 occasions. In 16 cases of functional heart murmurs, 42 were given ether, 2 cocaine and 2 chloroform. Seven of these took the anesthesia badly. In 4 cases of systolic murmur heard best at the base, 1 took ether badly. In 9 cases of arrhythmia all took ether well, but one of them had the arrhythmia increased. The severity of the operation did not appear to have much influence upon the effect of the anesthesia. In patients subjected to complete excision of the breast, herniotomy, resection of the appendix, etc., showing all forms of cardiac trouble, no bad effects could be determined on account of the duration of the anesthetization. [J. S.]

2.—Stengel believes that it is not yet positively proven that chloroform produces fatty degeneration of the heart and blood vessels. If it does the lesion is certainly extremely infrequent. In all cases it is doubtful whether the shock of the operation or the anesthesia is the immediate cause of the collapse. In 6 cases of myocarditis in which it was necessary to give ether, he has found

that, as a rule, they bore it well, although in some instances it was necessary to abandon the operation on account of threatened collapse. In an instance under his observation, of general arterial sclerosis with slight aortic disease, the patient, after etherization, died of progressive exhaustion of the heart muscle, which, at the autopsy, proved to be the seat of fibroid change. He mentions the interesting observations of certain gynecologists in reference to the influence of fibroid disease of the uterus upon the vigor of the heart. In some cases he is sure that the administration of ether has a temporarily beneficial effect upon the cardiac condition. Some remote results, however, may be due to the weakness of the heart. [J. S.]

3.—Mayo regards myocarditis as the most serious condition in reference to anesthesia. It is very difficult to determine its existence, and sometimes it is only discovered after the patient has died suddenly upon the table. He reports 2 cases, one of which died 48 hours after a cholecystotomy, and the other upon the table during an abdominal hysterectomy. The condition of the heart is not mentioned. In the third case of thyroidectomy for exophthalmic goitre in which the operation was performed with local anesthesia, the patient died 24 hours later. [J. S.]

4.—Hare calls attention to the great uncertainty regarding the dose of the anesthetic employed in surgical operations, because it is impossible to tell how much of the drug is dissipated in the surrounding air, and how much enters the patient's lungs. He believes that patients of exceptional height usually bear the anesthesia badly. The effect of ether is to increase arterial tension, therefore in cases in which the arterial tension is already increased it is not advisable. With regard to its administration he believes it is disadvantageous to use the rubber bag into which the patient respire, because it involves the inspiration of a large amount of carbon dioxide. Oxygen given with the anesthetic may possibly produce chemical changes in it. In myocarditic conditions chloroform should not be used, and nitrous oxide is strongly contraindicated. In certain forms of valvular disease there may be very marked improvement during the administration of the ether. [J. S.]

5.—Sewall has made careful investigations upon 430 persons taken without reference to their diseased condition, in regard to the presence or absence of the tracheal tug. He has found that a downward pulsation of the larynx immediately following systole of the ventricles, is an exceedingly common phenomenon. It is, however, as a rule, very slight, and only becomes unusually pronounced in cases of aneurysm. The non-aneurysmal tug usually occurs during the period of inspiration although this is not invariable. The statistics of these cases, which are given in tabular form, are as follows: In 245 males, 131 had no signs of pulmonary disease, but in 52 there a slight tracheal tug. Of these, 37 had the tug in a severe form. 112 cases pulmonary lesions, probably causing adhesions of the left pleura, were present, and 84 of these had distinct tracheal tug. In 71 cases it was pronounced. In several cases of tuberculosis of the left lung with cavity formation, the tug was absent. 185 women were examined, and of these 125 were normal. Only 30 of these had tracheal tug, and of these 30 only 10 had distinct tracheal tug. In 47 cases with probable adhesions of the left pleura, 34 had positive tracheal movements, which were marked in 20. In 9 cases of emphysema or arterial sclerosis the tug was present in 4. He concludes that in the majority of cases adhesions of the left pleura produce the tracheal tug, and that diminished extensibility of the lung may cause the same phenomenon. Also that in normal individuals it is possible that the diaphragm may pull down the heart and cause the aortic arch to press upon the left bronchus and cause a palpable tug of the larynx. [J. S.]

6.—Lartigau has been able to collect together 55 cases of sarcoma of the thyroid gland. He believes, however, that

the disease is more common than these figures would indicate. He reports a case occurring in a woman 45 years of age, who, 8 years previously, had noticed a lump in the neck. This gradually increased in size but did not cause any discomfort. Ten days before admission a second lump appeared in the left side of the neck, which was tender and produced some interference with the respiration on swallowing. The tumor was removed by operation and found to consist of an angiosarcoma replacing the thyroid gland. Active recurrence took place, and the patient finally died of asphyxiation. At the autopsy the findings were those of primary sarcoma of the thyroid gland and fibromas of the uterus and breast. The primary tumor was evidently a simple cystic goitre. In 51 of the cases of primary sarcoma, 35 had had goitre previously, and it is likely that the benign enlargement precedes the growth. Sarcoma of the thyroid appears to be commonest between the years of 40 and 70 and equally frequent in males and females. It is most common in the right lobe of the thyroid. The growth is very rapid and operative interference appears to be of little benefit on account of the great tendency to recurrence. Metastasis is quite common, especially to the cervical lymph glands, the lungs and the blood. In rare cases extensive tumor thrombi are found in the large veins. The commonest forms are round or spindle-cell sarcoma, although angio-sarcomata are not rare. [J. S.]

7.—Sturmdorf reports the following case: A woman of 35 suddenly developed sore throat, cough and hoarseness. Her general condition rapidly deteriorated; a collection of glands appeared in the left submaxillary region, and the abdomen protruded greatly. Physical examination showed enormous enlargement of the liver and spleen; marked reduction of the red blood corpuscles, great increase in the white blood corpuscles, and the characteristic changes in the blood of leukemia. There was also tuberculosis of the larynx, and the physical signs of tuberculosis of the right apex. There was considerable fever and from time to time the blood showed slight variations. The patient is still living, and a diagnosis of *spleno-myelogenic leukemia associated with tuberculosis*, has been made.

8.—Cohen and Spiller report the case of a man who had, at the age of 25, contracted syphilis. Thirteen years later he noticed nocturnal incontinence of urine. Six or seven years after this there was ptosis, and later inequality of the pupils. At the age of 52 some teeth were extracted, during which he felt no pain. At the age of 55 there was slight paralysis of one side of the face, disturbance of articulation, curious sensory disturbances, particularly extreme sensibility to cold water, loss of taste, impairment of vision, inequality of the pupils, diplopia, signs of myocarditis and slight disturbance of intelligence. The reflexes were normal; co-ordination perfect, and the muscles responded normally to electricity. Twelve years later the patient died at the age of 67. There had been progressive loss of strength, darting pains in the legs, which were relieved by warm applications to the abdomen, and death finally occurred as a result of uremia. Dr. Spiller examined the brain and cord, and found degeneration in the posterior roots in the lower cervical and upper dorsal regions. There was also a small area of degeneration of the columns of Burdach. There was also some degeneration in the extra-medullary portion of the fifth nerves and some of the other cranial nerves and their nuclei. The right cerebral peduncle was smaller than the left. The lesions justified the diagnosis of *atypical tabes*. They call attention to certain of the interesting symptoms: the slight disturbance of mentality, evidenced by a tendency to repeat stories and forget details; the springing mydriasis, and they conclude with an analysis of the literature of the subject.

9.—Fisher reports the following case of *typhoid fever* in a girl of 16, who, in the course of the disease, developed signs of *croupous pneumonia* of both lower lobes, which

were confirmed by the autopsy. Another case, a girl of 19 who developed signs of congestion of both lower lobes. There was some leukocytosis, great rapidity of pulse and respirations, and the patient died. An autopsy was not permitted. The third case, a boy of 16, was admitted with the signs of severe typhoid fever, muttering delirium, no leukocytosis, and on the 28th day of the disease there was some evidence of pulmonary complication and the leukocytes had increased to 45,000. He rapidly grew worse and died. The fourth case, a boy of 6, was admitted to the hospital, when he did not present the characteristic signs of typhoid fever, but developed consolidation of the lower lobe of the right lung. At the autopsy there was croupous pneumonia and swelling of Peyer's patches, apparently indicating convalescence from typhoid fever.

4. A Ship of the Veldt. ANDREW BALFOUR.
5. Reduplication of the Second Sound of the Heart. C. C. GIBBES.

1.—See Philadelphia Medical Journal, Vol. viii, No. 8, p. 279.

2.—Spencer divides the diseases of the right iliac fossa into (1) cecal distention, (2) perityphilitis and (3) appendicitis. He divides **appendicitis** into (1) acute perforating appendicitis, (2) suppurative appendicitis, sthenic, asthenic and septic extension, (3) relapsing and recurring appendicitis, and (4) chronic latent appendicitis with septic anemia. The treatment of cecal distention is entirely medical. Perityphilitis may be due to decomposition within the cecum or appendix or from other causes that leave no adhesions behind. In such a case medical treatment will be followed by cure. On the other hand, perityphilitic adhesions may be present, and, by their kinking, cause obstruction in the lumen of the appendix. Such cases require surgical treatment. In acute perforating appendicitis an immediate operation is the only means of saving life. In acute suppurative appendicitis, whether of the sthenic or the asthenic type, the appendix should be exposed as soon as the diagnosis can be made, by keeping outside the general peritoneal cavity, draining the abscess and removing the appendix at a later date. Relapses should be distinguished from recurring appendicitis by careful examination after the attack, and if signs of chronic appendicitis are found, the appendix should be removed at once. General septic anemia may be set up by a continuous latent appendicitis in which there is great danger of the disease not being recognized until too late for successful surgical interference. The author relies on the pulse rate in diagnosing between cases that require immediate operation and those in which medical treatment is indicated. If the pulse rate rises above 110 surgical exploration is strongly indicated while a pulse rate of 100 indicates medical expectant treatment. There are exceptions to these rules, however. In chronic cases the question of operation turns on careful palpation of the cecal region. If no deep-seated tenderness is discovered the case should be considered one for medical treatment. [J. M. S.]

3.—Tubby reports the case of a boy aged 9 years who was suffering from *traumatic separation of the lower epiphysis of the right femur*. The condition was treated by open operation and the epiphysis was retained in its place by a screw. There was also a fracture of the middle of the left femur. [J. M. S.]

5.—Gibbes considers that if both the aortic and pulmonary elements of the diastolic sound can be distinguished that the diastolic sound is reduplicated. It is not necessary that the component parts be separated by a distinct interval. He believes that the side of the heart that has to cope with the greatest amount of abnormal intra-arterial pressure takes the longest time in getting up

steam to overcome the said pressure and open the semilunar valves; it, therefore, begins its contraction before the other ventricle. The closure of the semilunar valves takes place, under normal conditions, at the moment when the intra-arterial pressure rises to a point higher than the intraventricular pressure. If, therefore, any alteration occurs in the relative aortic and pulmonary pressure, those valves would close first on the side on which the arterial pressure was in excess of this normal ratio. In his paper the author deals with those cases in which the pulmonary pressure is abnormally high. The author finds that, as a rule, the point of maximum intensity of the first portion is in the pulmonary area, and that the intensity of the second portion is greater in the aortic area. He records two cases in which there was increased intensity of the second portion of the reduplicated sound to the left of the apex. When an aortic diastolic murmur is associated with reduplication of the second sound, the murmur always follows the aortic or second portion. In mitral stenosis with an early diastolic murmur the same thing occurs; if reduplication is absent, the murmur accompanies the second sound and is called an early diastolic murmur; should reduplication be present, it follows the second or aortic portion of the reduplication, and is called a mid-diastolic murmur, the distance between the murmur and the pulmonary portion of the second sound depending on the amount of asynchronism present. In some cases in which the aortic portion of the second sound is very feeble, the murmur may drown it and appear to entirely replace it; the murmur being separated from the pulmonary second sound by a distinct interval. [J. M. S.]

BERLINER KLINISCHE WOCHENSCHRIFT.

July 8, 1901. (No. 27.)

1. Paroxysmal Tachycardia. U. ROSE.
2. Report of Cases of Pulmonary and Laryngeal Tuberculosis Treated from December 18th to April 10th 1901 at Karase's Polyclinic with Intravenous Injections of Hetol (Landerer). H. GUTTMANN.
3. The Advancement of Medicine Through Laryngology. GRABOWER.
4. Remarks on a Case of Aneurysm of the Aorta. LANDGRAF.

1.—Will be abstracted when concluded.
2.—The author gives a summary of the results obtained in cases of pulmonary and laryngeal tuberculosis that had been treated with intravenous injections of hetol, as prescribed by Landerer. The treatment was instituted in thirty-three cases and is recommended by the author. In cases of laryngeal tuberculosis there were microscopical evidences of improvement in portions of tissue that had been obtained by curetting. One case was cured and ten were markedly improved. Even in cases that did not terminate favorably there was at least transitory improvement. The dosage of hetol must be a guarded one, notwithstanding that no toxic phenomena are reported in these cases. Guttman recommends the hetol treatment in all cases of inelapent tuberculosis. [M. R. D.]

4.—Landgraf urges the importance of considering the involvement of the recurrent laryngeal nerve in cases of aortic aneurysm, and cites a case of his own in which he made the diagnosis of aneurysm of the thoracic aorta in an officer 43 years of age, simply from the pressure that the aneurysm caused upon the left recurrent laryngeal nerve and the effect upon the circulation in the left carotid and subclavian arteries. [M. R. D.]

July 15, 1901. (No. 28.)

1. The Question of Zomotherapy. C. FRAENKEL and G. SOBERNHEIM.
2. Cryoscopy of the Urine. H. KOEPPPE.
3. The Treatment of Aphasia. H. GUTZMANN.
4. Double Formation of the Lower Turbinate Bone. STURMANN.
5. Paroxysmal Tachycardia. U. ROSE.

1.—Treated editorially in the Philadelphia Medical Journal of August 10, 1901.

2.—The results of the author's investigations may be summed up as follows: In estimating the freezing point of the urine it is to be taken into consideration that not only the urines of the two kidneys may be dissimilar, but

also urines that have been secreted at different times; the urine that is emptied from the bladder, therefore, is practically a mixture of various urines, which must be borne in mind when determining the reaction and the molecular concentration. The urine of each kidney, therefore, should be separately obtained. The author states that, as a rule, the reaction of the human urine is acid in the morning, alkaline in the forenoon, again acid before the mid-day meal, alkaline again thereafter, and again acid during the evening and the night. He emphasizes the statement that the chemical equilibrium of the urine may be changed by the addition of a solution of salts, and that a change of reaction may take place under these circumstances to such an extent that a neutral urine, by the addition of an alkaline salt solution, may subsequently show an acid reaction. [M. R. D.]

3.—Gutzmann states that in speech exercises during aphasia individual syllables should be systematically practiced. Furthermore, it is important to have the patients perform writing exercises with the left hand, in order to prepare the brain for the speech exercises. Tactile and optical sensations should also be taken into consideration. He believes that, even in cases of long existing aphasia, the results are very encouraging. [M. R. D.]

4.—Sturmman reports a case in which there were visible three turbinate bones on the left side. The middle of the three bones occupied about the anterior half of the nasal wall, while above and posteriorly was seen the superior turbinate. The author states that in the human fetus, between the third and fourth months, there is superiorly a curved prolongation of the turbinate bones, which reminds one of the mallian, which later unwinds and utterly disappears. He explains the phenomenon in this case as due to a retardation of the above-mentioned metamorphosis occurring in the fetus. [M. R. D.]

5.—The author reports a typical case of apoxysmal tachycardia, in which there was no dilatation of the heart during the attack, although cardiac weakness was observed during the paroxysm. The author's case, as a whole, is an example of the assumption that paroxysmal tachycardia is to be attributed to a central neurosis. [M. R. D.]

DEUTSCHE MEDICINISCHE WOCHENSCHRIFT.

1. Topography of the Brain. WALDEYER.
2. Differentiation of Human and Animal Blood by Means of a Specific Serum. E. ZIEMKE.
3. Clinical and Therapeutic Investigations Concerning Pulmonary Phthisis. E. STADELMANN.
4. Concerning "Cancer a deux" and Infection with Cancer. R. BEHLA.
5. Biological Investigations of Natural Chalybeate Waters. O. ADLER.
6. Trauma and Extrauterine Pregnancy. L. SEELIGMANN.

1.—To be continued.

2.—Ziemke has made further studies of the specific biological blood reaction, having been furnished by Wassermann and Schuetze with two serums, (A and B, A having been prepared by somewhat more prolonged and more numerous injections of human blood.) The blood investigated was dissolved in a 0.75 salt solution or a 0.1% soda solution diluted until the color was a faint pink and the serum was added in a proportion of 1 to 10. He reports investigations of fresh fluid blood, of foul decomposed blood, dried blood as old as two years, blood in cloth, the spots dating back as far as 1878, blood in earth, on instruments, blood washed out of clothes where it had been as long as 18 years, blood from a cellar wall, blood stains on wood, and on glass, blood from a man poisoned with CO., blood on paper, ten months old, and blood stains on linen which had been exposed to the open air for several months. With serum A he had only one negative result (blood-stains made on a shirt in 1883) and in this case the solution had absolutely no color and evidently the blood was not extracted by the solution. With serum B he had seven failures evidently because the animal yielding this serum had not been so strongly dosed. The reaction when most striking occurred at once; sometimes there was only a very gradually appearing cloudiness. With other varieties of blood than human, he never got a reaction with the human antiserum. [D. L. E.]

3.—Stadelmann refers to the work of his assistant,

Meyer, in regard to eosinophile sputum and its relation to prognosis in phthisis. He could not confirm Teichmüller's results (extracted from *Deuts. Arch. f. Klin. Med.*, 1899). Many cases were seen that were certainly mild early phthisis that showed no eosinophiles in the sputum; in one case with rapid course there were always numerous eosinophiles and in many cases bacilli and eosinophile cells were found together in the sputum. Stadelmann thinks that contrary to Teichmüller's very definite statement that eosinophile sputum means a favorable case, one may say flatly that there is no known relation between the number of eosinophiles in the sputum, or even their presence or absence therefrom, and the stage, severity or other nature of cases of phthisis. Guacamphol is next discussed as a means of controlling the night sweats of phthisis. He gives it in doses of about 3 gr. in the evening and advances to as much as 15 grs. and finds that it has an effect equal to that of atropine and is harmless and had no unpleasant collateral or after effects. The active ingredient is camphoric acid, but Stadelmann believes that it acts better than camphoric acid. Pyramidon was used in doses of 3 to 4 grains twice daily (or larger doses) to control the fever of phthisis. The results were good in most cases, but it failed in a considerable number. Nevertheless Stadelmann considers it a very useful drug for this purpose but prefers camphoric acid to pyramidon in cases which tend to sweat as the plain drug tends to increase sweats while the camphoric acid preparation controls sweats. [D. L. E.]

4.—Behla presents a series of cases of "Cancer a deux" i. e. instances in which persons living in intimate contact with each other, but not related, died of cancer one after the other. He speaks of these cases quite freely as instances of infection of one person from another, and insists that there is perfectly satisfactory evidence that cancer is contagious in a limited degree, somewhat as leprosy is. He believes that there should be regulations to prevent the spread of cancer through direct contagion or fomites, and pleads for a special German institution for the study of cancer. [D. L. E.]

5.—Adler, in investigating the reason for the occurrence of a precipitate in Carlsbad water found that adding an antiseptic to the water prevented this occurrence and afterward found that bailing the water well had the same influence. He then studied the precipitate and found long spirilli in enormous numbers. After bailing water and seeing that it kept perfectly clear and no precipitate formed, he introduced some of the spirilli and a precipitate soon formed thus leading him to the positive conclusion that this precipitation of iron salts is due to bacterial action. A matter which is of considerable importance to the bottlers. [D. L. E.]

PRESSE MEDICALE.

July 17, 1901. (No. 57).

1. Adiposis Dolorosa. PROFESSOR DEBOVE.
2. Injections of Iodo-mercuric-cacodylate.

L. BROCC, CIVATTE and FRAISSE.

1.—Debove presented the first case of adiposis dolorosa which he had ever seen. The name, which was given the disease by Dercum in 1888, is particularly appropriate, representing, as it does, the two main symptoms of the disease. Women alone have been found subject to it. This case, a woman aged 80, the mother of 5 children, fell 15 years ago, after which accident an operation was performed upon her hip, some bloody fluid being evacuated. Since that time her legs have been weak. For three years afterward, and off and on since, to her 65th year, irregular metrorrhagia existed. Pain appeared in the left hip and lumbar region, always along the nerves. It is made worse by pressure. She grew stouter very gradually, weighing now 163 pounds, while she is under five feet high. The fat is in large masses about the malleoli, hips, calves, buttocks, abdomen, forearms, and backs of the arms, especially. This fat is only found in certain regions, and is not universally or equally distributed. The masses are, however, symmetrical and the pain appears in or near them. The prognosis is grave, as no treatment has ever cured the condition. But the patient may live years with it. Debove believes the condition is due to some disturbance in the fat regulating apparatus of the spinal cord. Thyroid extract will be given. [M. O.]

2.—Iodo-mercuric-cacodylate is made by neutralizing acid mercuric cacodylate by adding to it sodium iodide. It has always been given in injections, as diarrhea followed its in-

gestion. There was no smell of garlic to the breath. The doses given were 1 or 2 c.c. of a solution containing 3 cg. of sodium cacodylate to the c.c. The injections were given in the buttocks. This treatment proved successful when biniodide and calomel injections and mercurialunctions failed. In all, 49 cases of syphilis were treated. After a full exposition of the experiments, their success and their failures, they conclude that Iodo-mercuric-cacodylate contains sodic cacodylate, sodium iodide, and mercuric biniodide; that it is soluble in water, sterilizes at 120°, and mixes with blood-serum without producing any precipitation; that it is well supported in subcutaneous injection, without pain or abscesses; and that it is indicated in syphilis with marked lack of nutrition, with emaciation, neurasthenia, etc., in the rebellious secondary manifestations upon the skin and mucous membranes, when syphilis exists as a complication, and when the stomach will not bear mercury, in the tertiary stage.

July 20, 1901. (No. 58).

1. The Antitubercular Dispensary in Lille.

A. CALMETTE.

1.—Calmette relates the facts which led to the foundation of the Emile Roux Dispensary for Tubercular Patients in Lille, describing in detail the buildings recently erected. The purpose of the dispensary is to find those laborers who have tuberculosis, to treat them gratis, to distribute milk, food, and antiseptic spittoons, to obtain their absence from work when necessary, and to allow the carrying out of a general prophylaxis against tuberculosis. This idea has been followed in other cities of France, aided by public subscriptions. Questions are asked about the family and personal history, clothing, work, hygiene, home, etc. The examination of each patient includes measurements of the chest, weight, expectoration and thorough examinations of the lungs, heart, and larynx. Assistants visit the homes of the patients once a week. People in the same house are instructed in antitubercular hygiene. Bed-clothes, etc., are carefully disinfected. Some cases are sent to the country. Calmette hopes to teach the people by this means the best manner to combat tuberculosis.

[M. O.]

CENTRALBLATT FUER CHIRURGIE.

1. The Surgical Treatment of Thrombosed Varices of the Leg. W. KRAMER.

1.—According to the author, thrombosis occurs frequently in varices of the leg, and particularly in the superficial ones. This complication was once looked upon as a favorable occurrence and as leading to a cure of the venous dilatation; earlier surgeons have even attempted to bring about this condition artificially for therapeutic purposes. But our knowledge now of thrombosis leads us to regard it in these cases as an unfavorable complication on account of the recurring inflammations which lead to abscesses, ulcers, eczema and even fatal emboli. Improvements and cures have but very rarely been brought about by organization and calcification of such thrombi, and then only after weeks and months of rest in bed. As such surgical procedures as ligating the saphenous vein or its total extirpation have been instituted, the author believes himself justified to recommend a new procedure which is a safe one. If performed under rigid asepsis. This consists in making an incision into the skin and an incision into the varicose veins in their long axis and carefully removing the coagula. He reports fifty favorable cases in which there were no secondary hemorrhages, which he explained was due to the fact that the termini of the vessels were closed by the coagula. The operation wounds healed without fever or reaction and without fistulae, the scars which remained being narrow, painless, and in no case the seat of the ulcers or eczema. [M. R. D.]

REVUE DE CHIRURGIE.

June, 1901. (21me. Année, No. 6).

1. Symmetrical Lipomata in a Patient with General Paralysis of the Insane.
CHARLES FERE and MARTHE FRANCLION.
2. The Treatment of Stricture of the Rectum with Stenosis. ALFRED NAVARRO.
3. The Examination of the Blood as a Means of Surgical Diagnosis. JACQUES SILHOL.

4. Accidents Attending the Eruption of the Wisdom Teeth. MOTY.
5. Scapulo-humeral Arthrodesis. BOTHEZAT.
6. Genital Tuberculosis in the Female.
MARIE GOROVITZ.
7. The Treatment of Artificial Anus.

X. DELORE and M. PATEL.

1.—Féré and Francillon report a rare case of **symmetrical lipomata** occurring in a man of 51, with **general paralysis of the insane**, which followed a blow on the head two years ago. His general condition is good. Lipomata, symmetrical in position, are seen upon his arms and legs. Some have existed 20 years, others over 7 years; in both cases long before he became insane. They are all small and lobulated. The literature of the subject and the different theories to explain their occurrence are reviewed. Féré and Francillon believe that the usual antecedents of general paralysis, syphilis and alcoholism show a tendency to the development of certain disturbances of evolution, even before any signs of general paralysis appear. These tumors are not considered trophic changes, in any way connected with the general paralysis of the insane.

[M. O.]

2.—Navarro reports in full the histories of three cases of **stricture of the rectum with proctitis**. The first case was in a syphilitic woman of 38; the second, in a syphilitic man of 42; and the third, in a non-syphilitic woman of 32, following hemorrhoids. In all three, the strictures had almost produced stenosis. Navarro operated upon all of them, performing laparotomy, with extirpation of the affected part of the rectum *en masse*, leaving an iliac artificial anus. Strictures of the rectum may be found high up in the rectum, or in the sigmoid flexure, with all grades of dilatation above the stricture. He attaches the intestine, which is well stretched, between the iliac and the parietal peritoneum, after having performed torsion by the Gersuny method. Thus a true anal canal is made, which can be controlled by the patient voluntarily. An excellent result was secured in every case.

[M. O.]

3.—From a series of **blood examinations**, with estimations of the amount of hemoglobin, the number of red and white blood corpuscles, and their characteristics from cover-glass preparations, Sihol concludes that a patient with gastric symptoms, who presents a considerable diminution of hemoglobin, a notable decrease in the erythrocytes, marked leukocytosis, and irregular, deformed red cells, probably has a tumor of the stomach. If there are all of these things present, very irregular in form, the tumor is cancer. Leukocytosis in carcinoma has been noted, especially in carcinoma of the rectum. In a number of cases of cancer of the breast, bladder, and cardiac extremity of the stomach, leukocytosis was absent. With suppuration it always exists. Leukocytosis found in a case of appendicitis is a cause for immediate operation. From the small number of examinations made as yet, no definite conclusions can be drawn. [M. O.]

4.—Will be abstracted when concluded.

5.—Will be abstracted when concluded.

6.—Will be abstracted when concluded.

7.—Delore and Patel consider the **treatment of the true artificial anus**, not including suppurating stercoral fistulae. When a communication exists between the intestine and the outside air through the abdominal wall, an artificial anus, or true stercoral fistula results. At first the intestine is normal; later a spur forms opposite the opening and the mucous membrane atrophies. Surgical treatment will result favorably if no spur exists, when the openings are small, and when granulation tissue lines the wound; it will result unfavorably when there is a protruding spur, when the openings are large and when the intestinal mucous membrane covers the wound. Numerous useless extraperitoneal operations have been devised to re-establish the intestinal circulation. To close the external orifice extraperitoneally, compression, cauterization, sutures, with total closure of the wound, have all been attempted. The results were not very satisfactory. Nowadays the intraperitoneal operations are chosen, on account of the good results obtained. Three operations are employed, **lateral enterorrhaphy**, **entero-anastomosis**, and **enterectomy**. The technique of all three operations is given in full. Two cases of Professor Poncet, cured by enterectomy with the use

of the Murphy button, are described in detail. While entero-anastomosis is a benign procedure, it is not curative. Thirteen case histories follow, of patients in whom the Murphy button was employed. Delore and Patel conclude that the extraperitoneal methods of treating artificial anus should only be employed exceptionally, as they are often dangerous and incomplete. They are only to be done when no spur is present. Of the intraperitoneal operations, entero-anastomosis is useless, lateral enterorrhaphy may do good when the large intestine is affected; **enterectomy is the best operation of all**. Circular enterorrhaphy with sutures is rarely done, the Murphy button being now generally used. It is sure, safe and rapid. [M. O.]

BOLNITCHNAIA GAZETA BOTKINA.

June 20, 1901. (Vol. xli, No. 25.)

1. On the Symptomatology and Treatment of Perforative Peritonitis in Gastric Ulcer. F. K. VEBER.
2. The Connection Between Diabetes Mellitus and Insipidus and the Female Genital Organs and Pregnancy.
K. K. SCROBANSKI.
3. On the Physiology of the Pyloric Portion of the Dog's Stomach. A. I. SCHEMIKIN.

1.—Veber reports a case of **gastric ulcer** in a man 42 years old, who suffered from gastric disturbances for several months prior to the appearance of the ulcer. The latter was made evident by vomiting of blood three weeks before admission, and **perforated five days before the patient was brought to the hospital**. In spite of the perforation, the patient walked about the day following. When examined, he was found in a state of partial collapse. Facies Hippocratica was more or less marked. The pulse was rapid, but quite full. The abdomen was distended and tympanitic throughout. A very rare and hitherto undescribed symptom was observed, namely, **vocal fremitus distributed throughout the abdomen**. This symptom was attributed to the presence of free gas within the abdominal cavity. When the latter was opened a considerable quantity of gas, free from odor, escaped. The perforation was found on the small curvature near the pylorus and in contact with the liver, to which the edges of the ulcer became adherent, thus localizing the inflammatory process. The perforation was closed by three silk sutures and gauze drainage introduced. During the first two days the patient received nutrient enemata, but the condition of the rectum necessitated the administration of liquid food by the mouth. On the sixth day the wound of the stomach opened, and the entire food introduced came out through the fistula. The patient died from exhaustion on the ninth day after the operation. The autopsy revealed a large round ulcer of the stomach undergoing carcinomatous degeneration. The author suggests that in this and similar cases **jejunostomy might be the means of saving life**, as it would enable the patient to receive direct nourishment, at the same time affording rest to the stomach. With regard to the peculiar symptom observed, the opinion is expressed that abdominal ceecal fremitus can only take place when the abdominal cavity is filled with gas and free from adhesions of the viscera. It is due to the gas being in direct contact with the diaphragm, from which the impact is received and transmitted during articulation. [A. R.]

2.—Will be abstracted when concluded.

3.—Schemikin was led by a large number of experiments on drugs to the following conclusions: 1. The conditions determining the secretion of the pyloric portion of the stomach are entirely distinct from those of the fundus. 2. The masses of food remain in the pyloric portion for a short time, and pass through the pylorus in small portions. 3. The pyloric portion is, therefore, to be considered rather the beginning of the intestines than the terminus of the stomach. [A. R.]

The Therapeutic Value of Electric Light.—G. A. Kliatchkin (*Kazanski Vredinski Journal*, March, 1901) employed electric light in the treatment of neuralgias, artralgia as a result of gout, articular rheumatism and obesity, with remarkable success. From 16 to 32 candle powers were used. In the three cases of obesity the loss in weight amounted to 6 to 9 kilos within 2 to 3 months. One case of psoriasis of the head was cured in twenty-eight sittings. Altogether twenty-six cases were thus treated. [A. R.]

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

Fiftieth Annual Meeting Held at Philadelphia, September 24-25, 26th, 1901.

(Continued from Page 638.)

A Case of Ascites due to Hepatic Cirrhosis; Treated by Transplanting the Omentum Between the Peritoneum and Abdominal Wall; Result with Autopsy 8 months later. Dr. W. J. Roe, of Philadelphia, read this paper. The patient's abdominal cavity had been tapped 31 times before the operation was performed, averaging 760 ounces per tapping. There were 21 tapplings subsequent to operation, averaging 218 ounces. Microscopical examination of the ascitic fluid was negative. Post-mortem examination showed cirrhosis of the liver, absence of the right kidney and a very large horse-shoe kidney. The portal vein and its chief tributaries were found to be uninvolved. The etiology and literature have been freely alluded to. (This paper will appear later in the Philadelphia Medical Journal.)

Typhoid Fever in a Prematurely Born Child, by Dr. Harry C. Westervelt, Pittsburg. The speaker referred to the scarcity of well authenticated cases of this kind. Enteric fever in children had been frequently termed infantile remittent fever until its real nature became known. He reported the case of a woman who had typhoid fever in her third pregnancy, in whom the course of the disease was severe, but who recovered. An accident caused the birth of a fetus 7 months and 2 weeks old at the beginning of the third week of the mother's illness. The child presented the weazen old-man appearance of the prematurely born and no hope of its living was entertained. It was placed in an improvised incubator, the child's temperature being 103.8°. It had diarrhea and weighed but three pounds and 14 ounces. It was removed from the incubator and placed at room temperature, the temperature of the child varying for 17 days from 99.4° to 102°. At one time the temperature of the little patient was 106°. The temperature subsequently became normal and the child recovered, weighing 14¼ pounds.

Ruptured Tubal Gestation and the Physician. By Dr. John M. Fisher, of Philadelphia. The author stated that unfortunately but few cases come to the attention of the surgeon in time and it is only when grave conditions are present that he sees them. The responsibility is forced on every physician and there is nothing more important in any branch of medicine for him to know than to be able to make a diagnosis in these cases. As soon as the diagnosis has been made, prompt surgical intervention is indicated. The writer has repeatedly found patients in an exsanguinated condition and in no case should this condition have been recognized as anything else than ruptured ectopic gestation with concealed hemorrhage. Ectopic gestation with few exceptions is tubal. The most important cases are those combined with inflammatory conditions and their sequelae. In most of the author's cases the patients had previously miscarried. There may be but two symptoms for diagnosis before the time of rupture; namely, metrorrhagia, sterility of several years standing, following a previous pregnancy. Often, when the patients are subject to a severe strain, they are seized with collapse, acute anemia and pallor, the pulse being absent or rapid and flabby. There may be nausea and vomiting. The condition cannot be confounded with fainting which is of but short duration as well as its accompanying symptoms. In ectopic gestation the anemia is profound and persistent. A boggy swelling in Douglas's cul-de-sac is usually present, due to blood clots. The condition has been confounded with gastric perforation, intussusception, volvulus and appendicitis, in

which conditions however there is less anemia, a less erratic pulse, pain extending over a longer period of time, and the absence of the clinical evidence of pregnancy.

Post-Typhoidal Nephritis and Chronic Nephritis with Intercurrent Typhoid Fever. By James Ely Tally, of Philadelphia. The author discussed the renal complications in enteric fever, and stated that when they were present albumin was present in the urine in a large percentage of the cases. The albumin usually disappears but has been known to persist for years without nephritis. When there is a nephritis it is generally of the parenchymatous variety, and may also be hemorrhagic. He quotes statistics and stated that there have been many cases with urinary changes without the renal structures being involved, and vice versa.

A New Method of Performing Nephropexy. By Henry D. Beyer, of Philadelphia. Dr. Beyer stated that the disadvantages of operation for these cases are that the sutures cut and result in electrical injury to the kidney. He described a method devised by him which consists in encircling the kidney with a rubber tube inserted through the perirenal fascia and then bringing it out of the wound, securing it in an aseptic manner through gauze.

Statistics of Typhoid Fever at the Philadelphia Hospital from 1897 to 1899. By Herman B. Allyn, of Philadelphia. The author's observations comprise 181 cases of which 31 were fatal, 1 case being due to ruptured ectopic gestation. 14 cases died of progressive asthenia, 8 from pneumonia, 5 from hemorrhage, 3 from perforation, and 1 from ectopic gestation. The disease occurred in negroes to the extent of 1/5, which is responsible for 1/2 of the mortality. He advises the employment of separate wards for typhoid fever and pneumonia, and believed that in the future many cases will be saved by operation. (This paper will be published later in the Philadelphia Medical Journal.)

Amyotrophic Lateral Sclerosis, with the Report of a Case. By Thomas L. Coley, of Philadelphia. The case reported was an atypical one which is of particular interest as it had been under observation from the incipency of the disease and carefully watched during its course. It occurred in a man, 41 years of age, with intercurrent acute bronchitis and vague pains in the calf of the right leg combined with a dragging sensation. When the patient was 12 years of age he had been run over by a wagon which passed over his abdomen. Myelitis was excluded by the absence of vesical and rectal symptoms. There is no personal history of inebriety or of venereal infection. Coordination, station, vision and papillary reaction were normal. The knee jerk on the right side was markedly increased. Ankle clonus was present and the calf muscles spastic. The left knee jerk was also increased, but on this side there was no ankle clonus present. Finer movements could only be executed by the left leg. The case progressed presenting a typical picture of spinal spastic paraplegia. The absence of involvement of the long bones, vertebrae, and the bones of the head, and the approximately normal condition of the patient's lungs excluded osteoarthritis. The differential diagnosis between this case and many other nervous affections was carefully considered, as well as the literature relating thereto.

The Value of the Tallqvist Hemoglobin Scale to the General Practitioner. By M. Howard Fussell, of Philadelphia. The author recommends the Tallqvist test for hemoglobin estimation stating that upon comparing this test with those of Gowers and von Fleischl he has found a variation of but 5 per cent. He described the method, showed the color scale, and emphasized the fact that the test must be conducted in daylight.

Fracture of the Neck of the Femur, Report of a Case, X-Ray and Specimen. By Charles E. Thomson, of Scranton. Dr. Thomson showed the specimen of the head of a femur of a man, aged 62, who in August, 1899, had sustained a fracture by a rock falling upon him, and in whom no diagnosis had been made at the time of the injury. He had been in bed

three months when seen by the author, and an operation advised. The performed operation followed the method of Gillet, of St. Paul, which exposes the seat of the injury. The fracture was found to be a comminuted one. The pieces were removed, and a silver nail driven through the neck of the femur which held the fragments quite firmly. The limb was encased in plaster of Paris and a spica bandage applied. In five weeks the patient was allowed to move about. Later a sinus appeared and pus was evacuated. 18 months operation only a slight sinus persisted and the patient walked into the hospital unassisted with 90 degrees of painless motion. The patient finally died of heart disease.

The Pathology, Symptomatology and Treatment of Uremia. By David Riesman, of Philadelphia. The speaker discussed uremic hemiplegia, uremic aphasia, and the complications of mental confusion and uremic insanity. Uremia may produce hemiplegia and monoplegia without a cerebral lesion, as he has frequently found post-mortem in cases previously diagnosed as apoplexy. The treatment was carefully discussed and the author believed that in persistent cases the patient should be put in a bath of 110° and afterward in a hot pack.

The Etiology of Acute Dysentery. By Simon Flexner, of Philadelphia. Dr. Flexner spoke of the unsuccessful attempts that had been made to classify the varieties of dysentery. It now appears by bacteriological examination conducted in various countries, that there is a peculiar organism not normally present, but which is present in cases where acute dysentery exists. The organism resembles the bacillus of enteric fever, occurs in the intestines, can be obtained in the dejecta, and does not occur in the same situations in health. These observations do not exclude the ameba which causes a particular kind of dysentery, but the new organism is probably pathognomonic of the acute variety.

At the close of the afternoon session the Trustees and Faculty of the Medico-Chirurgical College gave a reception in honor of the Medical Society of the State of Pennsylvania, guests and visiting ladies, at the college building. In the evening a special lantern demonstration was given which comprised *The Life History of the Ovary*, by Dr. John G. Clark, of Philadelphia; *Skiagraphy in Supposed Sprains*, by Drs. George G. Ross and M. I. Wilbert, of Philadelphia; *The Various Types of Smallpox with Remarks upon Differential Diagnosis*, by Dr. Jay F. Schamberger, of Philadelphia; *Some Medical Uses of the X-Rays*, by Dr. M. K. Kassabian, of Philadelphia, and the Kromskop, by F. E. Ives, of Philadelphia. Following the lantern demonstration, the Medical Club of Philadelphia gave a reception to the Medical Society of the State of Pennsylvania, at the Hotel Stratford.

The following officers were elected for the ensuing year: President, Dr. T. P. Ball, of Lock Haven; Vice-Presidents, Dr. Walter Lathrop, of Hazleton; Dr. A. S. Harshberger, of Lewistown; Dr. R. W. Stewart, of Pittsburg, and Dr. J. K. Weaver, of Norristown. Secretary, Dr. Cyrus L. Stevens, of Athens, and Treasurer, Dr. George Benson Dunmire, of Philadelphia. The outgoing President, Dr. J. P. Davis, was elected a Trustee. Dr. W. H. Hartzel, of Allentown, is Dr. John H. Musser's successor as head of the Committee of Arrangements and Credentials.

The next annual convention of the Society will be held in Allentown, Pa.

The Wills' Eye Hospital Ophthalmic Society met in Philadelphia May 13th, 1901, Dr. Conrad Berens in the chair. Dr. P. N. K. Schwenk presented a case of **dislocated cataract** in a man of 35, who had been struck in the eye thirty years before. Dislocation into the anterior chamber, accompanied with symptoms of secondary glaucoma, had occurred one week before the case was seen. There had been no irritation of the other eye. Dr. Berens referred to a

case in his clinic. The patient, a man of 47, had received an injury of the eye thirty years previously. He had poor vision until a few days before he appeared at the hospital, where he came for relief from severe attacks of pain. The globe was markedly swollen in comparison with the other eye and intraocular tension was greatly increased. There was ciliary tenderness of the good eye with hyperemia in the optic nerve and macular region. Enucleation was performed. Examination of the eye showed that the crystalline lens was dislocated downwards and forwards. The iris was atrophied, the ciliary body degenerated, and there was secondary glaucoma. The interesting point was the long period during which such a dislocated lens can remain inert. His theory was that an exudate of lymph had formed between the lens and the iris, the symptoms of secondary glaucoma being produced by a blocking up of the fluids of the eye. Dr. Charles A. Oliver presented a case of **dislocated lens into the anterior chamber with symptoms of acute secondary glaucoma**. The patient was struck in his right eye with a boxing glove eighteen years previously, becoming blind in a year's time. The eye was not painful until four days ago. The pupillary area was blocked by a cataractous lens that was bulging into the anterior chamber. Vision was limited to a point of light perception in the lower temporal field. The lens was readily extracted through a section made through the lower periphery of the cornea with a wire loop, without the loss of any vitreous. The wound healed in 48 hours. The other eye was healthy. Dr. Schwenk stated that he intended to remove the lens in addition to doing iridectomy in cases of glaucoma. This procedure he deemed desirable, provided there was no probability of severe hemorrhage. He believed that such a dislocated lens produced secondary glaucoma more frequently than any exudate, and pointed out that it was a hard foreign body in the anterior chamber. Dr. Oliver stated that glaucoma complex arises from many conditions. In the traumatic lenticular type the eye is usually quiescent for a long time, when suddenly some slight injury occurs, by which the more or less opaque lens is thrust into a false position—such as the pupillary area, by which the lymph flow between the chambers is stopped. In such cases he has frequently performed and advised immediate removal of the lens. His experience has been that totally dislocated lenses remain in the vitreous for years without any gross symptoms appearing beside uveal disturbances; but should they get into the line of flow of the intraocular fluids and cause lymph blockage, glaucomatous symptoms must be expected. He believed the plan of combining peripheral iridectomy with extraction of the lens to be useful in appropriate and carefully chosen cases, citing a successful example under his care. Dr. William Thomson presented a case of **exenteration for orbital sarcoma** in an old man of 79. He exhibited a photograph of the condition before operation, showing enormous masses of sarcomatous material filling the orbit and protruding from it, following the removal of the eye some two years before. The tumor-mass was found attached to the periosteum of the external, superior, and inferior walls of the orbit. Dr. Oliver gave a brief account of a case of **orbital sarcoma** involving the frontal, ethmoid, and sphenoid sinuses and the antrum, which he had removed by breaking into these cavities from the orbit. The socket granulated thoroughly into shape, and there has been neither recurrence nor metastasis. Dr. Berens called attention to some very interesting points of diagnosis in such cases, especially those elicited on palpation.

Society Reports: The Section on Practice of the College of Physicians and Surgeons held its regular meeting Monday evening, October 14th, when the following papers and case reports were read and discussed. Dr. J. A. Scott reported a case, and showed a specimen of an **Aneurysm of the Aorta which ruptured into the Pericardium**, which was discussed by Drs. Hare, Spiller and Steele. Dr. Jos. Sailer read a paper on "**A Case of Malignant Endocarditis**"

and Brain Abscess with Unilateral Kernig's Sign." This paper was discussed by Drs. Packard, Stengel, Hare and Clarke, especially as to what constituted Kernig's sign, and where to draw the dividing line between its presence and absence. Dr. Alfred Stengel made a report on "Sodic Purpura," and showed photographs illustrating the condition. Following this paper a very interesting discussion on Methods of Keeping Case Records in Private Practice, by Drs. F. A. Packard, Louis Starr, J. P. Crozier Griffith, Alfred Stengel, and J. K. Mitchell, closed the scientific program of the evening.

The Section on Gynecology of the College of Physicians of Philadelphia met Thursday, October 17, at 8.15 P. M. Dr. C. P. Noble read a paper upon an Improved Suture for Anterior Colporrhaphy, Dr. O. H. Allis read a paper on Intestinal Anastomoses with the illustration of methods and instruments, Dr. H. D. Beyer reported a case of Fibroid Tumor of the Cervix Uteri, with presentation of the specimen, and Dr. G. E. Shoemaker reported a case of Uterine Fibroma.

At the University of Pennsylvania Medical Society meeting in the University Hospital, Friday, October 18, at 8.15 P. M., Dr. A. O. J. Kelly exhibited a patient with an Intrathoracic Tumor, Dr. Edward Martin read a paper upon Abdominal Affections Characterized by Sudden Agonizing Pain, and Dr. Joseph Saller read a paper on the Relations between Tuberculosis and Hodgkin's Disease.

Manhattan Dermatological Society. A regular meeting was held on Friday evening, October 4th, 1901, at the residence of Dr. Oberndorfer, No. 1037 Lexington avenue, with Dr. Gotthell in the chair. Dr. Gotthell presented a case of *favus corporis* in a child of seven months. Three typical patches had existed in the interseapular region for four weeks, without any subjective symptoms or knowledge of infection on the part of the parents. Dr. Coeks presented a baby of two months, with redness and scaldiness of the lower abdomen, buttock, thighs and legs for opinions as to its syphilitic nature. Dr. Klineh believes it syphilis, owing to the involvement of the entire lower extremities. Dr. Abrahams and Dr. Bleiman call it *eczema intertrigo*. Dr. Sobel classifies these cases as *dermatitis erythematosa eczematoides*. Dr. Oberndorfer calls it *intertrigo* with more intense manifestations than usual. Dr. Geyser considers it *intertrigo* and not syphilis. Dr. Weiss states that it is a clear cut case of *seborrheic eczema* of the new born, the lesions in the inguinal region and inner surfaces of the thighs being modified by moisture. Dr. Gotthell also called it *seborrheic eczema*. The general opinion prevailed that the absence of rhagades, coryza, palmar and plantar lesions, and of enlargement of the liver and spleen spoke against syphilis. Dr. Coeks presented three cases of syphilis, a mother and two daughters. Seven months ago the mother presented herself with a chancre, syphilide, iritis, and mucous patches. Despite the most explicit directions as to the dangers and consequences of further contagion, the daughter of 13 years was brought three months later with a chancre of the right tonsil and a syphilide; four months afterward the second child showed a syphilide and a specific pharyngitis. Dr. Sobel remarked that instances of family syphilis were not uncommon and very deplorable. Dr. Weiss stated that it would be advisable to have syphilis classified by the local health boards as a reportable disease in the same manner as tuberculosis. Dr. Gotthell said that infection through the mouth is not uncommon and often explains many obscure cases. Dr. Abrahams presented a woman with *parasitic eczema* of ten years duration, situated on the abdomen and thighs. In addition, the flexor surfaces of the forearms showed a *papular eczema* very suggestive of *lichen planus* on account of the central depression in some of the lesions. Dr. Klineh thinks it a combination of *eczema* and *lichen*. Dr. Bleiman says that the thighs and genitals are *eczema marginatum* and the arms *lichen*. Dr. Oberndorfer states that it is an atypical case of *psoriasis*. Dr. Sobel calls it *eczema mycotic* on the trunk, *papular* on the forearm. The latter regions show the

retrogressive *eczema papules* which, as Gotthell states, so closely resemble *lichen*. Dr. Weiss considers it *eczema marginatum* aggravated by acute attacks. Dr. Gotthell excludes *lichen* and *psoriasis* and calls it a *mycotic eczema*. Dr. Abrahams showed a girl of thirteen years with *herpes tonsurans maculosus et squamosus*. The face and body presented scaly patches of various shapes and sizes. All were agreed on the diagnosis of *seborrheic eczema* mainly on account of the involvement of the scalp, post-auricular regions and forehead, the thickness of the scales, and the infiltration of the skin. Dr. Bleiman presented a woman with *vittiligo* of the arms, face and body. Dr. Oberndorfer presented a man with a *gumma* of the *glans penis*, to demonstrate how difficult it often was to differentiate from ulcerating chancre. No history of a previous syphilitic infection was obtained. Dr. Weiss advised rapid and heroic treatment. Dr. Gotthell remarked that histories were useless in such cases and that a diagnosis must be made from what is seen. Dr. Sobel showed a patient with *eczema marginatum* of the suprapubic region and thigh. Dr. Abrahams presented a child with a *papular scaly eruption* of almost the entire body with a diagnosis of *chronic papular eczema*. Dr. Coeks would call it *seborrheic dermatitis*. Dr. Oberndorfer terms it *lichen planus acutissimus* complicated with *seborrheic eczema*. Dr. Bleiman says it is *keratosis follicularis* and Dr. Gotthell believes it to be *congenital follicular keratosis*.

VRATCH.

July 7, 1901. (Vol. XXII, No. 27.)

1. Ruptures of the Uterus During Labor and Their Treatment. V. N. ORLOFF.
2. Old Russia. Changes of the Body-temperature and Pulse Under the Influence of Various Baths of the Same Temperature and the Effect of the Material of the Bath Tub on the Cooling of its Contents. I. I. MAKAVEEFF.
3. On the Purification of the Air of the Yards and Streets of St. Petersburg. I. M. IAKOVLEFF.

1.—Orloff reports 6 cases of rupture of the uterus in multipara during protracted labor. 2 were incomplete and 4 complete. All recovered after appropriate treatment, except one, the woman dying on the 8th day, of peritonitis. Statistics and observations of other authors are cited and the usual treatment discussed. [A. R.]

2.—Makaveeff studied on himself the effects of mineral baths on the body temperature in one of the bathing resorts of Old Russia. He found that baths of 32 R. (40C.) increase the internal as well as the external temperature of the body, although not in the same proportion, the temperature of the surface of the body being higher than that of the rectum. In this respect, the strongest effect is noticed in the case of general diluted mud-baths, then general salt baths, less so in pure mud-baths and weaker still in mixed or sitz-baths, the latter having the weakest effect of all. During the first 15 minutes both the external and internal temperatures are lowered. The cooling of the bath depends largely on the material from which it is made. Brass, zinc, iron and cast iron are very good conductors of heat and therefore cool the bath quickly; marble is less of a heat conductor than the above but still great, especially in comparison with wood which is the worst conductor of all and therefore the best material for a bath-tub. Many other observations are described in detail, but they are of interest only in connection with the resort. [A. R.]

3.—Iakovleff points out the unsanitary condition of St. Petersburg brought about by defective plumbing and improper disposal of sewage. By means of strips of filter paper impregnated with acetate of lead and dried, he was able to detect various quantities of sulphuretted hydrogen in the atmosphere in and about dwellings. To this condition he ascribes the exceedingly high rate of mortality which reaches 22 to 30 per 100. [A. R.]

POLITICAL ASSASSINATIONS

In Some of Their Relations to Psychiatry and Legal
Medicine.*By CHARLES K. MILLS, M. D.,
of Philadelphia.Professor of Mental Diseases and of Medical Jurisprudence in
the University of Pennsylvania.

The assassination of President McKinley has caused horror and alarm throughout the civilized world. It has also awakened widespread interest in the subject of political assassinations, of which we have had so many examples during the last decade—in Spain, France, Italy and the Orient. This interest cannot be regarded as merely morbid. In the community at large it is founded on the interest which everyone who is law-abiding has in the protection of human life and property and in the preservation of government and of society. At the root of the general concern is the doctrine of self-preservation, the first law of nature. To the student of medicine, of law, and of history, the subject of political assassination has a true scientific interest. It leads him to consider the criteria of mental soundness, the workings of the unbalanced mind, the springs of human motives and the character of the times in which the assassinations occur. Every such assassination is a terrible historical episode, and one inclination, born of the wish for enlightenment, is to turn to history for the annals and to legal medicine for the analyses of similar crimes.

Although it has been the incitement to the choice of my subject, this paper will not be concerned chiefly or even largely with the assassination of President McKinley; nor shall I take up at any length the study of the assassin Czolgosz. This event will be used only as one of many, the article being based on a brief and perhaps too hasty study of about fifteen historical cases, beginning with the assassination of Henry III. of France by Jacques Clément in 1589.

A glance at the historical cases used in the preparation of this paper shows that the assassins can be conveniently divided into four classes: (1) sane conspirators, (2) assassins clearly recognizable as insane, (3) degenerates who are not insane, and (4) degenerates of doubtful sanity.

Among sane assassins, however depraved, may be classed the Orloffs and their confederates, who in 1762 brought about the death of Peter III. of Russia for the usurper Catharine. It is generally believed that the actual assassins were members of the Orloff family. In the same category should be placed the assassination of Paul I. of Russia in 1801. It is supposed that he was assassinated by Count Pahlen, General Beningsen, Uwarow, or other nobles. The obscurity as to his real assassin results from the fact that he came to his death in a darkened room during a quarrel. A conspiracy was formed by the above-mentioned noblemen and many others, to put an end to the capricious despotism of Paul. It was at first intended only to urge his abdi-

cation, but during an argument with Paul his ungovernable temper precipitated a hand to hand struggle, during which the lamp went out, and when it was relighted the Emperor was found to have been strangled. No punishment was inflicted. Gustavus III. of Sweden also lost his life probably at the hands of a sane conspirator, although a man of erratic character and violent passions. Gustavus was assassinated in 1792 by John Jacob Anckerström, an ex-captain of the Swedish army, who had conspired with others against the crown because of the King's efforts to curtail the power of the nobles and of the Senate. He shot the King with a pistol loaded with broken bullets. John Wilkes Booth should also be ranked among sane conspirators and assassins. The assassination of President Lincoln in 1865 was the result of a conspiracy of which Booth was the moving spirit. Booth might perhaps be classed as an alcoholic degenerate, having inherited a craving for alcohol which showed itself in periodical outbreaks; or he might, like his father, be regarded as an erratic dramatic genius, but nothing in his life history or in his crime compels the diagnosis of insanity. Alexander II. of Russia was assassinated in 1881 by a band of Nihilists. They were undoubtedly conspirators, but little is known as to their mental status. They were presumably sane, although some of them not improbably belonged to the degenerate class to which a large number of the violent among the revolutionaries of all countries can be relegated.

Among assassins whom I would class as clearly insane are Ravallac, Louvel and Guiteau. Henry IV., the greatest of the Bourbons, was assassinated in 1610 by Ravallac, by stabbing. What is known of Ravallac makes for the diagnosis of insanity. It is said that in his youth he became a notary's clerk, and later tried school teaching and other pursuits. Imprisonment for debt brought on sickness and delusions. He was subject to attacks of mental excitement. Shortly after his release from prison he joined the order of Feuillants, and afterwards that of the Jesuits. Louis Pierre Louvel in 1820 assassinated the Duc de Berry, son of Charles X. and heir to the French throne. Louvel in his childhood and youth was an invalid, but was docile and good tempered; as he grew older he became morose, taciturn, eccentric, melancholic and the victim of fixed ideas. His mind became possessed with the idea that the Bourbons were the destroyers of France, and that it was his duty to exterminate them. He was a saddler, and at one time was in the service of the chief saddler of Napoleon at Elba. He followed the Emperor to Waterloo, and after Napoleon's fall was in the service of Louis XVIII. Besides his monomania regarding the Bourbons, a number of facts indicate his eccentricity or insanity. At one period of his life his only pleasure was in singing hymns in the temple of the Theophilanthropists.

Charles Jules Guiteau, who assassinated President Garfield in 1881, was insane, an opinion which I expressed before his trial and which I have continued to hold. It is justified by a study of his life history, by his conduct after the assassination, and by the results of the autopsy and microscopical examination of his brain. I have not here the space to

*Address at the Atlantic City Academy of Medicine, Oct. 11, 1901. I am indebted to Mr. Walter M. Van Kirk for valuable assistance in collecting data for this paper.

review in any detail the case of Guiteau, which abounds in interest both from the standpoint of psychiatry and of medical jurisprudence. Krafft-Ebing ranks Guiteau among his illustrations of *paranoia politica*. He certainly belonged to the type of insanity which is now generally designated as *paranoia*. My own view is that which was also held by Folsom, that he was a *paranoiac*, probably in the first stages of general paresis, a not unrecorded combination.

At the age of nineteen he left school and entered the Oneida Community, where he remained for five years, then left for a few months and subsequently returned and remained for another year, at the end of which time he withdrew from the community, and went to New York, where he contemplated the establishment of a daily journal to be called the *Theocrat*. In a letter to his father, written in 1865, speaking of his project for the establishment of a *Theocratic Press*, which was to provide the whole country with daily religious instruction, he claimed that he was in the employ of Jesus Christ and Company. The same letter abounded in similar insane extravagances. He studied law, was admitted to the bar, and practiced in a pettifogging way in New York and Chicago. He married, and afterward committed adultery to procure a divorce. In 1874 he entered a ridiculous suit for one hundred thousand dollars against the *New York Herald*. In 1875 he had a project for reviving the *Inter-Ocean*, a bankrupt Chicago paper, of which he was to be the editor. In 1875, apparently in a moment of maniacal excitement, he raised an axe to strike his sister. A physician at this time said that he was insane, and advised that he be taken to an insane asylum. He afterwards traveled about the country delivering trashy lectures, maintaining that he was a great evangelist. In 1879 he published a book of lectures called "Truth, a Companion to the Bible." In the Presidential campaign of 1880 he wrote a speech which he once delivered in part. After the election of Garfield he began to put in important claims for office. He first applied for the position of Minister to Austria, and subsequently for that of Consul-General to Paris. He urged his claims in the most absurd manner, both by letter and in person, upon President Garfield and Secretary Blaine. According to his own way of putting the matter, he now "conceived the idea of removing the President."

The conduct of Guiteau, both during his trial and on the scaffold, was consistent with the idea of insanity. I was present at his execution, and shall never forget the dramatic scene presented when this man stood with the noose ready to be placed around his neck upon the scaffold; how he chanted the foolish rhymes of his own creation, "I am going to the Lordy," until, overcome with emotion, he wept and swayed to and fro like the leading character in a religious meeting characterized chiefly by excitement; and how in the speech which he was allowed to prepare and deliver, he posed as a hero and a martyr. I was present also at the autopsy of Guiteau, which was made a few hours after his death. The appearance presented by his cerebral convexity was similar to that which is sometimes seen in general paresis. The pia presented an

opaque appearance, which disappeared in part as the fluid oozed away. The convolutions were probably somewhat atrophied, and it will be remembered that subsequent microscopical examination of blocks of brain tissue were made independently in different cities, and the report on each was to the effect that the brain was decidedly diseased. Many gyrals and fissural abnormalities were noted in the gross examination of the brain.

Our third and fourth classes of assassins—degenerates not insane and degenerates doubtfully sane, may be considered together. Glancing backward in our historical review, a word might be said about Jacques Clement, the assassin in 1589, of Henry III. of France. He was a fanatic, probably a degenerate, and may have been mentally unbalanced, as history shows that his health had become disordered by his bad habits. Others, probably degenerate on the evidence at command, although the data are meagre and not satisfactory in some instances, are the assassins of Marat, of Carnot, of Canovas, the Premier of Spain, of the Empress of Austria, and of King Humbert.

Marat was assassinated in 1793 by Marie Anne Charlotte Corday. She stabbed him in the heart while he was taking a bath, it is said, as a treatment for syphilis. On her trial she admitted and justified her deed. She was of noble family, of great beauty, and bore a striking resemblance to Marie Antoinette. It is said that the idea of slaying either Robespierre or Marat came to her while posing for the artist David as Judith preparing to slay Holofernes. At the beginning of the Revolution she became infected with revolutionary ideas, but at the outbreak of the Reign of Terror she was overcome with horror at the acts of the Jacobins. Lombroso, after a rapid inspection of the skull of Charlotte Corday, affirmed the presence of an extraordinary number of anomalies, an opinion which he holds is confirmed not only by the monograph of Topinard, the anthropologist, but also by photographs of her skull. Lombroso gives in detail the result of his investigation of what he regards as striking cranial anomalies, among a large number of these being the enormous size of the orbital cavities, especially the right, which is lower than the left, as is the whole right side of the face.

President Carnot, of France, was assassinated in 1894 by Cesare Giovanni Santo, an Italian baker. Santo in appearance was brutal and degenerate, and the alleged cause of his crime was the refusal of the President to pardon certain anarchists. Senor Canovas, Premier of Spain, was assassinated in 1897 by shooting, by Michel Angino Golli. Golli is said to have come of an honest family, but was himself a fanatical anarchist. He served for a time as a soldier, but his military record was bad; he was indifferent and disobedient, and was sent for three years' service in the disciplinary battalion. The Empress of Austria was assassinated by stabbing with a file at Geneva, Switzerland, by Luigi Lucchoni. He was an anarchist who boasted of his hatred of the rich and of those in power. While in prison he addressed a letter to a Milan newspaper in which he expressed a fear lest he be mistaken by Professor Lombroso for a degenerate. King Humbert of Italy

was shot in Monza, Italy, by Gaetano Bressi, an Italian silkweaver, who was living just previous to his crime at Paterson, New Jersey. He is said to have been of moody temperament.

The crime of Czolgosz is so recent as scarcely to need a recital in detail. He shot President McKinley in two places, one of the wounds eventually proving fatal. He carried the weapon concealed beneath a handkerchief, which was wrapped around it and his hand. It has been suggested in some quarters that this seemed to point to an accessory or accessories. Czolgosz, however, consistently denied that he had accessories, and it was quite possible for him to have made use of the handkerchief in the manner in which he did, without any assistance. It is not improbable that he got the idea of concealing the pistol from the published accounts of the manner in which Santo killed President Carnot. Santo wrapped his knife in a copy of the Parisian paper, the *Figaro*, and the police, it is said, believed that he had in his hand a petition which he wished to present to the President, and thus allowed him to gain access to the President's carriage.

With regard both to the mental and physical condition of Czolgosz little has been published. The alienists by whom he was examined, however, united in pronouncing him sane, and no evidence has been adduced to the contrary. The brief statement of one of these alienists, Dr. James W. Putnam, of Buffalo, in *The Philadelphia Medical Journal* of October 19, 1901, records him as a young man of twenty-eight, with a former history of good health and steady habits; educated in the public schools until fifteen; at intervals a wireworker, blacksmith's helper and farm hand; thrifty in that he had saved \$400 in six years; a voter at the age of twenty-one, and about this age a convert to anarchism, and a disbeliever, according to his own avowment, in religion, government, law, God and marriage. At his examination he said that he killed the President because it was his duty, and that he was glad that he had done it. Dr. Putnam states that Czolgosz did not at any time sham insanity; that although he refused to discuss his crime with his lawyers, he did discuss it with others; that in conversation and appearance he is more intelligent than the average Polish laborer; and that physical examination showed his pulse 82, temperature $98\frac{1}{2}^{\circ}$, tongue clean, skin clear, patellar reflexes normal and heart normal—a record so far as it goes of excellent health. Certainly we have no evidence in anything that has been published that Czolgosz is insane, nor according to the meagre accounts of him does he present any special signs of degeneracy which separate him from sane men and women of his class. Whether those who hold views such as he has proclaimed regarding the individual and society are entirely normal may be regarded by many as doubtful, but according to the rules applied in a study of the question of sanity or insanity in such cases, with the evidence before us, his insanity cannot be admitted. He probably belongs, however, to the class of degenerates.

Let us delay here for a moment to discuss briefly degeneracy and insanity in the relations to the class of criminals under consideration. Degeneracy and insanity are by no means interchangeable terms;

the degenerate are not all insane, nor are all the insane degenerate. Degeneration as Maudsley puts it is the undoing of a kind, and the term is now often used to indicate a change from a higher to a lower kind, a process of dissolution. The degenerate is the one who has been reduced or relegated to a type lower than the standard normal individual. Degeneracy is generally regarded as shown by certain bodily landmarks called stigmata, as difference in stature or in the length of limb; irregularities of the skull and face; deformities of the palate, ear, genitals or other parts. On the mental side the evidences of degeneracy are "general want of harmony between volition and instincts; instability; excess or deficiency of the emotional sensibility; obtuseness; slow mental development; defective mental development; defects of speech; all stages of mental weakness down to idiocy." The landmarks of degeneracy may be present in the normal or even in those of high intelligence, but they occur in a large percentage of the idiotic, insane and criminal. Insanity, however, is not to be determined merely by a study of the indications of degeneracy. The diagnosis of insanity should be made by a study of the psychical state, and the mental symptoms presented by the subject of the investigation. In order to be classed as a degenerate in the technical sense, one whose degeneracy places him below a generally accepted normal standard, it is not necessary simply that the physical landmarks of degeneracy be present, but in addition the individual must present satisfactory evidences of psychical aberration and dissolution. Degeneracy, in other words, is relative, and the term should not be used with too wide an application when discussing questions of insanity and criminality. Not a few of the political assassins, whose crimes have startled the world, are degenerates in the fullest meaning of the word as used by Lombroso, and some of them may be classed as both degenerate and insane; while others should not fall in the latter category.

Youthful degenerates later in life not infrequently become instances of easily recognizable insanity with systematized delusions; still later passing into forms of dementia. Our attention is fixed by the immature years of the assassins here considered, and of many other historical cases. Jacques Clément was twenty-five years old, Ravallae thirty-two, Ankarström thirty-one, Charlotte Corday twenty-five, Wilkes Booth twenty-seven, Santo about twenty-one, Golli thirty-three, Lucchioni twenty-five, Bresei thirty-one and Czolgosz twenty-eight. Louvel had reached thirty-seven years and Guiteau forty-two, and in both of these cases the insanity was well defined.

Sanity and insanity like degeneracy are also relative terms. At the one end of a series is the individual with the highest grade of mental development and health, at the other end is the idiot; between these extremes are all degrees of mental health and degeneracy. For the purposes of the law, and even at times for those of medicine, it is necessary to make an arbitrary line on one side of which are placed the sane and on the other side the insane. When to draw this line is determined simply by an application of the data of psychiatry to each individual case. The marks of degeneracy are

not without value in arriving at a decision as to sanity or insanity, but it is necessary that they should be used and interpreted by one who has the requirements and acumen to make a correct interpretation.

Assassins clearly recognizable as insane frequently are to be classed under the type of insanity now commonly designated paranoia. This variety of insanity is known by various names: as monomania and primary delusional insanity. In its fully fledged form it is an easily recognized mental disease with a method of development, a course and a termination familiar to every alienist, but it is not part of my present design to discuss paranoia at length. Prominent among its clinical features are in its period of development a tendency to self-analysis, obsessions and morbid impulses, and as the disease becomes more fully organized, delusions of suspicion and persecution and false ideas of self-importance, these appearing successively, or it may be hand in hand. The dangerous delusion that the paranoiac has a mission, social, religious or other, frequently comes into the foreground. The transformation and exaltation of the paranoiac's personality is associated with the idea that he and others are the victims of persecution. Instead of paranoiacs with well systematized delusions and other manifestations constituting a familiar clinical picture, in every community are to be found degenerates, more out of institutions than in them, who are perhaps best described as paranoiacs in the making. These form a large proportion of the cranks and crack-brained of popular speech. They are in reality weaklings, but owing to their egotism and self-assertion they often impress others as they are themselves impressed with ideas of their virtue or valor.

Krafft-Ebing has well described many of these cases in his chapter on *paranoia politica*. In history as well as at the present time, he says, we meet with many who, dissatisfied with the social conditions surrounding them, feel themselves called upon to reform the world, or at least to supplant the old with something new. The main difference between the real genius and the pseudo-genius is that the genius has not only the mental organization to see the defects of his surroundings, but also the mental force to expand his ideas for its betterment in a logical and useful way. The pseudogenius, whose mental development is one-sided, resembles the genius in the originality of his views and his power of induction. In the expansion of these ideas, however, he becomes irrational and eccentric. The clinical manifestations of this disease present an infinite variety. In many the intellectual force is slight and their mental product of such a nature as to bear the stamp of crankiness and not of genius. If esthetic and ethical defects coexist, their ideas are often a priori monstrous or immoral. In many cases, however, the mental development is brilliant, though one-sided, and then the danger is imminent that the thoughtless crowd accepts the single brilliant thought as a new gospel. Very many of these abnormal subjects remain throughout life theoretical reformers and leaders of new movements, but this is but the prodrome of a severe and incurable mental state, *paranoia expansiva*. Such individuals easily lose the remnant of their mental stability under the

suggestive influence of others or of troublous times. Then they are impelled to carry their ideas into execution and become leaders of riots or founders of new parties or sects. The stage of incubation is long, often reaching back to early youth. A dreamy fantastic behavior, a tendency to build air castles of future greatness, great self-consciousness with seclusion from the vulgar herd, premonition of a great mission in life and brooding over inventions or social problems are related in the early history of these cases. Frequently neuroses as epilepsy and hysteria are to be noted. The forensic importance of this class is indeed great, as they often do not stop at words or mischief making, but keep on to deeds such as attempts to murder those in power, mistaking the representatives of a system for the system itself.*

Was Czolgosz one of a band of active conspirators? Had he associates and accessories? He has avowed himself an anarchist, but he has also, at least up to the time of the writing of this article, continued to insist that he acted on his own initiative; that he was not in a plot with others, and that the method was his own, as is also the responsibility for the crime. Probably the truth about this matter will never be known, although some contributions to the discussion may be forthcoming in the future in the shape of insane confessions and sane accusations. While some facts seem on superficial examination to point to accessories, on the whole I think it is probable that the man was alone in his crime, so far at least as direct intrigue and assistance are concerned. Even if it is admitted that he was not a member of any organization of conspirators to take the life of the President, he may have been the unconscious dupe of other conspirators with this aim. With regard to several of the historical cases here cited, it has been frequently asserted that the assassins were the unconscious dupes rather than the conscious agents of others. Jacques Clément is supposed to have been influenced by Spain, or by members of the League. It has also been asserted that the Jesuits took advantage of the unbalanced mind of Ravallac to instigate him indirectly to the assassination of Henry of Navarre, formerly the leader of the Huguenots, and who was, as the assassin may have been led to believe, still the enemy of the Catholic Church. Ravallac, however, in spite of tortures inflicted upon him, refused to confess that others were involved with him in the crime. Foolish efforts were made to have Louvel confess that he was the tool of England, but in spite of repeated application of torture he scoffed at the idea and denied having had any accomplices or instigators. It is probable that while Czolgosz's inspiration to commit the crime came from the study of anarchy and in part from listening to anarchistic speeches, that he was not directly in conspiracy with individual anarchists. The astute and cunning conspirators who are found in anarchistic and other circles are usually able to pick out from those who attend their coteries or who perhaps hang on the outskirts of their movements, the type of man who will be most likely incited to deeds of violence by their teachings. It

*Extracted from the Wien. Med. Blätter, Nos. 48-49, 1892, and the Rev. Ins. and Nervous, March and June, 1893.

is only necessary to let events take their course, to allow the seed sown a little time to ripen. I do not of course believe that the insistent and persistent denial by an assassin that he has accomplices should be taken as evidence that this is the case. My conclusions are reached by a different process, from a study of the assassin himself and of known facts regarding those with whom he is supposed to be acting.

No possible doubt can exist that in some cases the assassins of recent years included in our list have actively conspired with others and have both predetermined and prearranged the crimes. This was true of the Russian Nihilists who killed Alexander II, and of the assassins of King Humbert and of Senor Canovas. It may have been true of the assassins of Carnot and the Austrian Empress; these two assassins, like Czolgosz, were avowed anarchists, but may have acted in part on their own initiative. In my enumeration of sane conspirators I have already included the assassins of Gustavus III of Sweden, of Peter III and Paul I of Russia, and of President Lincoln.

A word might be said here with regard to the subject of insanity and conspiracy. Because a man is a degenerate, or even insane in the full sense, it does not follow, as many seem to suppose, that he is not capable of taking part in a conspiracy. Well planned, and unfortunately in some instances well executed conspiracies, have been formed by the insane inmates of asylums; and many of the half insane degenerates take as naturally to conspiracy as the normal man does to open enterprise.

What should be done with political assassins? Let us glance at what has been done with some of them in the past. When Jacques Clément stabbed Henry III in the abdomen, the King instantly wrenched the knife from his body and struck his assassin in the face with the bloody weapon, and a moment later the attendants and guards fell upon the assassin, who died pierced by twenty sword thrusts. Ravaillac, after a speedy but formal trial, was torn to pieces by horses. Anckarström was flogged on three successive days and then beheaded. Charlotte Corday, Louvel and Santo were guillotined. The assassins of Peter III and Paul I were protected and some of them even rewarded by the legates of the crimes. Booth was shot to death by Boston Corbett, one of the soldiers engaged in his pursuit. Of the Nihilists who killed Alexander II of Russia one was blown to pieces by the same bomb that killed the Czar, and five others were hanged two days later. Guiteau was hanged after a prolonged and tedious trial. Golli was executed, probably by garroting. Lucchioni was imprisoned for life, as according to the laws of the Swiss canton in which the crime was committed the death penalty could not be inflicted. Bresci was imprisoned for life, but soon committed suicide. A few days after the publication of this article Czolgosz will be electrocuted.

Some seem to favor the infliction of punishments that rival those of pestmedieval times; others cry out for execution without even the form of trial, and still others after the form but not the substance of a trial. Just punishment should be inflicted,

but it should be done by due process of law. Whenever possible, efforts should be made to reach those who are the real instigators of the crimes. It is probable, however, that in the case of the insane and degenerate the infliction of the death penalty does not always lead to the results which are hoped for in the protection of society. Krafft-Ebing says of the political paranoiacs that they do not fear death, as it stamps them as martyrs in the eyes of their followers, and he holds that the true punishment for them is the asylum. If the asylum means a place in which they can be safely confined for the rest of their lives, this opinion is for the insane correct. I have seen two men of the class referred to by Krafft-Ebing hanged, and have had interviews with others a short time before their execution. In all cases they have shown an indifference to death, and in some have looked to the scaffold as a place where they could pose as heroes and martyrs. The great publicity which is given to the details of execution certainly does much harm.

What should be done to prevent a recurrence of political assassinations? This, it will be seen, is quite a different question from that of what shall be done with assassins. One meets everywhere those who have ready methods of solving the problem. One newspaper contributor, for instance, suggests that the anarchists, whether assassins or not, be collected together on an island and be allowed to fight out their ideas as to individual rights until they exterminate each other. Something perhaps might be done as regards the prevention of individual attempts by a system of international policing, something by a careful guard over immigration. It is the proud boast of this country that it is an asylum for the oppressed of all nations, but this does not mean that it should be the dumping ground for the depraved and degenerate, the vicious and criminal. Liberty to think, to speak and to print is one of our greatest boons, but this should not mean license to incite to violence the immature, the degenerate and the insane. After all, permanent relief can only come through a study of the causes and cure of crime, through the spread of right principles, and through the elevation of the masses.

Pulsating Empyema.—II. Desplats reports the case of a girl of 14, who had a sudden chill, with pain at the base of the chest, on the left side. (*Journal des Sciences Médicales de Lille*, May 25, 1901). Fever persisted for three days. In 24 hours there was already absolute dulness over the lower half of the left chest, with a distant respiratory murmur. There were no rales. The fever grew less but the dulness increased and rales appeared. Exploratory puncture gave creamy pus, which contained pneumococci. The dyspnea and bulging of the interspaces increased, and a distinct pulsation was felt. An incision was made and three liters of pus evacuated. Recovery followed, after two rises of temperature, after which the amount of purulent discharge increased. Desplats considers three points in this case of exceptional interest; the rapidity of onset, with the size of the effusion; the distinct cardiac pulsations of the empyema *en masse*; and the probable occurrence of an interlobar empyema under the fourth rib, near the sternum, which explained the rises of temperature 8 or 10 days after the pleurotomy. Desplats believes that croupous pneumonia occurred at first, with secondary interlobar pleurisy. This went on to abscess formation, and opened into the general pleural cavity, causing the empyema. [M. O.]

THE CZOLGOSZ CASE.

By EDWARD C. SPITZKA, M. D.,

of New York.

Undoubtedly measured by the standard of public decency the spectacle furnished by the Czolgosz trial contrasts most favorably with those offered by the legal and quasi-legal procedures ensuing after the murders of Lincoln and Garfield. It remains a question, however, whether under other circumstances some of its features would not have to be regarded as—to say the least—inadequate to the cause of ideal justice. Gross violations of the prisoner's legal rights, such as through ignorance of law, natural in a court composed as that which tried the real and suspected assassins of Lincoln and several members of his cabinet, was composed, namely of military men, were avoided. Nor was there evident on the part of the prosecution any such vindictive spirit as was shown in the trial of the assassin of our second martyr President, which notoriously went the length of mutilating exhibits by removing from a prisoner's letters such portions as might have suggested or supported the theory of mental disease. The crime of Czolgosz was so evident, its elements so repulsive, and its deliberation in its association with anarchist views so manifest, that a perfunctory prosecution would have sufficed to secure a verdict entailing the extreme penalty of the law. It will all the more redound to the credit of the district attorney, that in favorable contrast with like officers, under like circumstances, he had the prisoner examined in regard to his mental state without "instructions to find for the prosecution," and so examined prior to having the prisoner indicted. He would, in case of a finding of evident insanity, have been in a position to evade responsibility for such a farce as the Guiteau trial constituted.

The prisoner's attitude rendered the position of the court an awkward one, and it evidently felt this keenly. Czolgosz's refusal to plead, or even to reply to ordinary questions, made the position of his counsel an even more difficult one. The latter was under the circumstances limited to one possible line of defence, that of insanity involving irresponsibility. How to establish such, nay, how to justify the mere surmise, where the subject of inquiry willfully closes the only channel by which thoughts and reasoning are exhibited to the examiner, is a problem rarely presented to the alienist, and when presented, one of the most difficult to solve. Obstinate mutism has therefore proven one of the more successful measures of the simulator. It could, however, prove of no value in the present case as sustaining the insanity plea, owing to the crass inconsistency of mutism with the mental state at the time of the shooting. It hence proved but an additional stumbling block to any defence whatever. That the prisoner's assigned counsel felt himself reduced to a purely formal defence need not surprise one. And when the physicians, who at his own request, examined this imposed client, reported the latter to be not insane, the last prop of a material defence fell away and the counsel cannot

be accused of dereliction of duty on the above ground.

In regard to his closing address, however, I find a most objectionable feature. It was not necessary for the counsel to anticipate the prosecuting attorney by calling up the emotions of the jury on behalf of the martyr victim of his client. The district attorney scarcely went so far as the defendant's counsel in this respect. The pathetic recital of President McKinley's noble qualities, the loss the country sustained, the bereavement the counsel asserted himself to have personally suffered, were all made truthfully. But we question whether such appeals would have been regarded as essential to his securing a verdict of guilty by the public prosecutor. All the less were they in place in counsel's final address to the jury in whose hands the fate of his client was shortly to be placed.

The crocodile tears, which certain notorious pettifoggers of criminal courts are so apt at calling forth when required, are regarded justly with equal detestation and contempt. How shall the tears of genuine grief shed by Czolgosz's counsel as he mentioned the bereavement inflicted by his client, be judged? From the general standpoint of humanity they may be condoned, but from the strictly professional standpoint the pathos manifested on so unusual an occasion and in a way so contrary to a client's interest does not seem to be in harmony with the dignity, gravity and propriety otherwise marking the proceedings.

Regarding a point which was and is of far greater importance than the retributive punishment of the single assassin, I believe that our police and legal machinery has proven grievously inadequate. I refer to the existence of possible accessories, since to my mind there are features in the crime which point to their existence. The subterfuge of the bandaged hand* strikingly suggests a female source; at all events the prisoner does not exhibit the appearance of intelligent spontaneity this dastardly trick presumes. His itinerary of the four months preceding the murder brought him in collusion with persons notoriously associated with an international set of anarchists. Barely a year ago this very set was affiliated with the notorious anarchist's leader, Malatesta, and about the time of his visit as well as shortly thereafter there were several warnings, anonymous and otherwise of a plan aiming at the leading crowned heads. Two of these warnings mentioned the President of the United States as included in the list of intended victims. The warnings were too nearly simultaneous and preceded from too widely separate quarters, South America, the States and Europe, to have been fortuitously coincident practical jokes. The event has proven the reality of such a plot; no doubt some of the selected soloists experienced stage fright at the critical moment, and not all defalcators could be substituted with as prompt effectiveness as was Sperandio by Bresci, but within a few weeks of Czolgosz's deed, we have Pietrùcci's suicidal attempt revealing prematurely the mission of Romalino; we have further the suicide of de Bungal and

* I do not attach any weight to the trivial circumstance of the handkerchief being a woman's.

the arrest of several bearers of related missions at Hamburg, in Buenos Ayres, and at St. Petersburg.

The method of arresting suspected accessories of Czolgosz, followed by the police authorities of several of our cities, smacks of the same panicky stupidity that induced the authorities to grant a paranoic in the President's native city a guard of soldiers to protect him against the phantoms of persecutorial delirium. It was at random and so stupidly initiated and carried out, that instead of furthering the interest of justice, it simply furnished opportunity for damage suits on the part of the parties arrested—which these last are too wise to avail themselves of.

To closet such persons in jail together with full opportunities for reading the daily papers and seeing emissaries passing and repassing from one to the other, as was done in several instances in connection with this case, were worthy of the palmiest days of Abdera. Solitude, time and uncertain expectancy are motive springs for confession and betrayal of associates, whose employment has at all times been regarded as essential to the end of justice in case of dangers menacing the safety of the State. But to not one of these has recourse been had and the authorities lost prestige with the public, and the awe of the guilty by this random and inconsistent procedure.

It so happens that for what may be good reasons the prosecution failed to avail itself of a means calculated to effectively trace and punish accessories, if Czolgosz had such. Though an unconstitutional law the Conspiracy Law of the State of Illinois rendered that State the more eligible one to conduct the trial of Czolgosz in.

In the first place, it provides for the case of criminals guilty of crimes in other States and extraditable from such States to its own custody when the crime committed in the latter is suspected to be the result of a conspiracy in the State of Illinois. In the second place, the collected facts point to the location of the presumptive conspiracy in that State. In the third place, the loopholes in the law open in other States for a defence of quibbles are closed in Illinois. No matter how objectionable in principle the legislation securing, and how servile the motives of the judicial advisor suggesting (at the time of the Haymarket bomb-throwing) them, these features are advantages the prosecution would have been justified in availing itself of; what may seem to justify its neglect to do so is at once a curious and a humiliating fact.

A prominent police official in Chicago has with apparent good reason become the subject of investigations whose ultimate result promises to become a prosecution of a more serious character. No better opportunity to rehabilitate himself could have happened than the discovery of criminals so vengefully regarded by the public as conspirators against our Executive. Accordingly he was all activity. His opponents fearing the overshadowing of their energy by a successful *coup*, did everything in their power to throw discredit on his efforts, and the old proverb about honest men com-

ing to their own was illustrated in an inversion: when the authorities fall out, the guilty escape.

As to the mental calibre of Czolgosz, generally speaking, I recognize nothing particularly differentiating it from the average persons belonging to his class, or if you please, "party." There is the same contracted view of the individual's relations to his surroundings; the same false ideal of heroism, and, what must not be lost sight of, the same obstinate loyalty to his associates, a feeling which will probably conduct him through the ordeal of punishment without revealing their identity and share in the crime. Like most anarchists* he has not acquired any skilled trade, nor has he, in fact, shown any capacity in other directions than the coarsest kind of manual labor. I believe that the scene which has been related in the press as his "collapse on arriving in jail" may bear a different interpretation. His movements are described as an unloosening of all his limbs in jactatory movements. They occurred when the attendants seized him to put the prison garments, which are of a somber hue, on him. Czolgosz imperfectly comprehending his sentence, whose terms it must be remembered, are in this State indefinite as to the precise time of execution, may have apprehended that this sentence was being carried out instantaneously, and his conception of the influence of the lethal current by "suggestion" as it were, was illustrated in the movements which struck casual observers as so singular.

In a study made some years ago relative to mental epidemics and historical periods as influencing insane mentality as well as its sane counterpart, it appeared incidentally that assassinations have not become more frequent in the present era. The social disease of which these acts are mere surface manifestations has been coeval with the history of civilization, and under different guises has produced corresponding results at all times.

From the cuneiform inscriptions to the modern book page, the records of assassination are distributed with the same surprising evenness as are the analogous ones of suicides and of epidemic insanity. That assassination has ceased to be a relaxation of the opulent and ruling classes as it was in the days of the Ptolomies, Seleucides, Perseus and Jugurtha, and occasionally also in the later days of the Plantagenets and the Borgias, is paralleled in other fields. In those days it required a strong provocation of the ego to nerve a proletarian against a governor or a king, as it did a slave to avenge a beloved master by slaying Hasdrubal, and the peasant stab the rapacious tax collector L. Piso. Later religion supplied the motive, and from the fanatics who poinarded the chiefs of Kufa down to the Ravallacs, Gerards, Clements and Damiens, its strong influences were felt. Still later these gave way with the developing prominence of economical and social questions to socialistic, atheistic, libertarianistic and chaotic views generally. That they contained devotees in their ranks such educated men as was for example the assassin, Nobiling, is

* Kibaltshitsch among the not unrelated group of Nihilists and a well known mechanic of New York City, are among the few exceptions.

among the incomprehensible features of the subject. Equally is the fact that any historical student, for such he was, could ever have dreamed of any good result accruing from assassination. A summary of the facts elicitable from the figures in the sequel might be made the basis of an educational chart for the use of anarchists and other terrorists.

TABLE SHOWING MEANS EMPLOYED BY ASSASSINS SINCE THE USE OF GUNPOWDER HAD BECOME GENERAL.

	Number of cases in which person aimed at was killed.	Number, ditto wounded and survived.	Number of cases in which exclusively persons not aimed at were killed or wounded.	Number of attacks with no result.	Total number of failures.	Grand total.	Percentage of success.
Dagger, sword, or other weapons for cutting and stabbing.	28	8	0	5	13	41	68.2
Firearms.	28	13	2	39	54	82	34.1
Bombs, mines and explosion-methods generally.	2	0	6	1	10	12	16.6
Other methods.	0	1	0	0	1	1	
	58	22	8	45	78	136	12.6

		In successful attempts.	In failures to kill person aimed at.	Total.

Of 588 murders attempted and consummated, including all instances in which those prominent in history have been killed from political, dynastic or other reasons connected with the public station of the victim, 277 may be termed assassinations in the accepted narrow meaning of the word, equivalent to the attentat of continental writers. Of these, 155 succeeded in so far as the death of the victim ensued. Of these, 52 were avenged by the legal execution of one or more of the perpetrators, 20 by instant death at the hands of guards or the public by the killing of the flying assassin or by

his suicide; a total of 75 cases in which death was retributive. In 5 additional cases execution occurred for later crimes, the perpetrator having escaped the immediate consequences of the former, and in 3 further cases suicide similarly ended the criminal's career. In 61 cases execution, in 6 suicide, and in 3 retributive assassination avenged unsuccessful attempts.

The "mortality" by legal and other retributive measures was therefore over fifty-five per cent. Excluding those cases where the deed was done under protecting influences, as were Czolgosz's and Masamiello's for example, over eighty per cent. of the assassins perished.

SOME RESPIRATORY CONDITIONS DEPENDENT UPON GOUT AND OBESITY.

By J. M. ANDERS, M. D., LL. D.,

of Philadelphia.

Professor of Medicine and Clinical Medicine in the Medico-Chirurgical College

The abnormal conditions presented by the lungs in obesity have not been as thoroughly studied in the past as the subject deserves. Their pathogenesis is not clear, although it may be assumed that they are caused principally by the mechanical effects of the deposits of fat throughout the body. On account of the abnormal masses found in the thoracic and abdominal cavities, the breathing space is greatly encroached upon, hence the respiratory capacity must to an equal extent be diminished. The weight of the external fat deposits, likewise tends to restrain the respiratory movements, while the depositions in the upper portion of the abdominal cavity prevent full diaphragmatic excursions. Upon actual measurement, I have frequently observed the respiratory capacity to be less than two and one-half inches in obese subjects, and it is obvious that such interference with lung-expansion must excite dyspnea upon muscular exercise, upon over-distension of the stomach and even when occupying a recumbent posture, as during sleep.

Dyspnea is more marked in the anemic than in the plethoric variety of obesity. There is in these instances an inordinate incapacity for exercise of all sorts, probably for the reason that the fat globules are more loosely grouped together, with greater abundance of intervening material in the form of "sero-mucous fluid," which interferes with and even almost paralyzes muscular action. The blood changes presented by this form of obesity also contribute to the production of this symptom. The so-called anemic dyspnea is familiar to clinicians, and I have found that there is considerable reduction in the hemoglobin percentage as well as a well marked oligocythemia in these cases. While the symptom dyspnea is attributable in great part to mechanical interference with the respiratory function, the weakening influence of the anatomical alterations—muscular as well as hematologic—in this kind of obesity also share in its causation.

On the other hand, in the plethoric form of obesity in which there appears to be compensatory hypertrophic changes in the muscular structure, dyspnea is less marked and often surprisingly slight. The

general bodily vigor is as a rule plus in this group of cases. There is a thoracic symptom belonging to over-fatness, to which I wish to direct special attention in this connection; it is pain in the sub-scapular and intra-scapular muscles. This pain may be quite acute, especially on making a strong voluntary effort to maintain an erect posture or upon attempting to exercise the arms. It was described by one of my patients as a feeling as though the "flesh had grown fast to the bones." The pain may be localized, although more commonly it extends across the back from side to side. In one of my patients it was excited by merely lifting the arms above the level of the shoulders. This patient also complained at intervals of a rather acute, though fugitive pain, which passed through the base of the right side of the thorax, especially upon attempting unusual muscular exertion. It is interesting to note that the fat deposit was decidedly larger on the same side of the thorax, and also that a reduction of the bodily weight entirely relieved the pain. These must be discriminated from other forms of pain, notably the rheumatic and neuralgic varieties, and in attempting this the etiologic influence of over-fatness must be accorded due weight.

The marked restriction of the thoracic excursions in respiration and the enfeebled heart action often present in these cases, combine to induce a passive, venous congestion of the bronchial mucosa. Thus it is common to witness in obesity a hyperemic (passive) bronchitis with troublesome cough and oftentimes copious, mucoid expectoration. The cough is aggravated by muscular exercise, particularly if active, proportionately with the increased disturbance of the circulatory equilibrium on which this form of bronchial catarrh depends. It is also present in severe paroxysms after a night's rest and recumbency, which allows of the accumulation of mucus in the tubes. Acting either as aggravating or exciting causes of the cough may be mentioned, sudden vicissitudes of temperature, strong wind currents, especially if combined with low temperature, irritants of all sorts, however slight, in the inhaled air, damp dwellings and prolonged exposure to wet and cold.

The physical signs are variable. As a rule, the expansile movements of the thorax are greatly restricted for the reasons before pointed out, and the tactile fremitus and percussion note are enfeebled in consequence of the presence of an abnormal deposit of fat. On auscultation there is generally observed a weakened vesicular murmur or more rarely it may be exaggerated. Adventitious sounds are also audible, as moist rales, and I have noted that sibilant rales and various forms of whistling sounds usually predominate, the presence of much mucous notwithstanding. This form of bronchitis is rarely encountered in the plethoric variety of corpulence, but it is not uncommon in the anemic variety, particularly if, as happens, the phlegmatic temperament is found in association. The bronchitis of anemic obesity runs a slow and often irregular course, unless the underlying causative condition is removed by appropriate treatment.

Closely connected with this variety of bronchitis, and to some extent dependent upon it, is asthma.

This affection is usually regarded as of cardiac origin in obese subjects, and I doubt not that transient insufficiency of the heart muscle, more especially of the left ventricle, leads to an accumulation of blood in the pulmonary area, including the bronchial mucosa that excites marked temporary dyspnea. The same result, however, is favored by the accompanying defective respiratory capacity which is especially pronounced during sleep or while the patient is in the recumbent posture. Not to be overlooked are certain other factors as the blood changes, that diminish the oxygen supply to the tissues and create "air hunger" as well as the uric acid diathesis. There is also an asthma in connection with obesity due to gastric disturbance, particularly in patients who are gluttonously inclined; this is associated with high position of the diaphragm and considerable gastrectasis. The attacks usually occur at night after hours of sleep as under other circumstances. The gouty state is often an accompaniment of obesity and there are excellent reasons for thinking that both of these conditions are at times dependent upon inadequacy of the liver function. Burney Yeo (*British Medical Journal*, June 15) has pointed out that hepatic inadequacy is productive of the gouty state, since this organ is concerned in the metabolism of nitrogenous material and in the formation of urea and uric acid. I have a fixed belief that it may also lead to obesity owing to the interference with the glyco-genic function of the liver. I have observed cases of asthma due to obesity that were associated with hepatic inadequacy; they are generally curable by attention to the underlying causative liver condition and a rearrangement of the diet so as to overcome the obesity. Treatment directed to obesity alone may increase the tendency to asthma in some cases. In such it may become needful to counteract the tendency to the formation of uric acid, which probably acts as an excitant, in order to effect relief.

As to the frequency of the complaint in polysarcia there is little definite information to be found in the literature, although the prevalent view is to the effect that it is comparatively common. Personal experience and observation incline me to the opinion that the severe paroxysmal dyspnea seen in obesity is in many cases not a true asthma, and that not uncommonly these pseudo-asthmatic seizures are relieved by assuming and quietly maintaining for a brief period the erect posture. There is here little or no vasomotor spasm and no true spasm of the circular muscular fibres of the bronchi. Neither do we note the characteristic sputum coincidently with the subsidence of the attack, nor the leukocytosis that is so important and constant a feature in typical asthma. Genuine asthma, however, occurs in obesity, although it is probably less common than is supposed. Of a total of 256 cases of obesity that fell under my care, the history of associated asthma was obtained in 13, or a little over 5 per cent. These cases of asthma were met with only in extreme polysarcia. In forming this estimate I carefully endeavored to exclude those instances before alluded to, in which the symptom dyspnea was alone in evidence and readily relieved

by change of posture, i. e., from the dorsal to the upright position.

These are not to be looked upon as cases of genuine asthma, but rather as instances of congestive dyspnea, due primarily to the obesity, although excited by the decubitus. Obviously the treatment is that of the primary condition or obesity.

Of the thirteen cases that I treated, five were apparently cured for periods of time ranging from one to three years, and four were greatly improved as the direct result of dietetic and other regiminal measures directed to the obesity in a successful manner. Three of the patients failed for want of moral courage to carry out the various elements entering into the required treatment. The remaining case of the series belonged to a special class to which I have alluded previously.

The effect of the usual measures prescribed to bring about a reduction of the bodily weight in the latter instance was to aggravate the asthma both as to the frequency and the severity of the attacks. The patient developed symptoms of the gouty state, including a highly colored and extremely acid urine. There were also present evidences of hepatic torpor, such as constipation, pale dejecta, a furred tongue and slight enlargement of the liver with tenderness to palpation over the hepatic area. This case was finally cured by the use first of a course of calomel in fractional dosage, followed by the alkaline mineral waters, especially Saratoga Vichy. The diet was considerably restricted more particularly in the direction of the proteids; physical exercise was continued. Most probably the exacerbation in the asthma was in this case due to the excess of uric acid in the blood. Possibly it may have been occasioned by the gastro-hepatic condition *per se* (asthma gastrica). In my opinion the order of events is as follows, in the majority of cases at all events: the hepatic inadequacy produces the gouty state, as Yeo contends, and the latter induces the asthmatic symptoms.

Concerning the hepatic enlargement, it must be recollected that this may also arise as a secondary event in obesity. The question of the relation of asthma to polysarcia is somewhat obscure. My own tentative conclusions are: (a) That asthma occurs in about five per cent. of the cases of obesity; (b) That it only occurs in extreme polysarcia; (c) That there is present a gouty state or history in most cases in which true asthma is secondary to obesity; (d) That about fifty per cent. or one-half of the cases are curable by overcoming the causative condition.

Referring briefly to the bronchial affections in which gout figures principally, it may be pointed out first that this disease and obesity are closely associated. Among 196 of my cases of over-fatness, gout was either in association or had occurred among the antecedents in 97 cases, or 49.5 per cent. There was a history of rheumatism in 30 per cent. of the same group of cases, and it is highly probable that many of the latter were also instances of gout, so that the actual percentage of cases of overweight in which there is a gouty inheritance or a family history of this affection is even higher than

the figures given above. The prominent part played by gout in the causation of that form of asthma met with in obese subjects has already been sufficiently emphasized. Gout occurring independently of obesity may also cause asthma, and according to my observation and experience it is a more potent factor than is supposed. The attacks of asthma rarely alternate with acute gouty manifestations, while in other cases they coincide with the acute gouty seizures. More commonly asthma is met with in chronic and irregular forms of gout and the most certain method of relieving such cases is by an antipodagral plan of treatment. It is commonly associated with gouty bronchitis and emphysema, and it may happen that the asthmatic attacks are either combined or alternate with the bronchitis or other gouty manifestations. According to certain authors asthma occurring in association with the gouty diathesis, is to be looked upon as a functional nervous disorder which is engrafted upon the latter.

If, however, it is desired to successfully treat this form of asthma, it must be regarded as being closely connected etiologically with podagra. I hold that asthma may be directly dependent upon the transient, irritant action of the uric acid in the circulating medium favored by the decubitus, and hence it is one among the numerous nervous phenomena of gout.

The dry, chronic bronchitis of Laennec is recognized by most writers as a distinct variety of bronchitis due to the gouty state. When chronic bronchitis is associated with advanced gout, it is easy of recognition and its treatment obvious. It is to be regarded as a part of a general fibroid process in some cases. It is often found in association with gouty affections of the larynx and pharynx.

There are cases of the gouty state in which the more conspicuous lesions throughout the body (heart, kidneys, etc.) and characteristic articular changes are absent; they are, however, associated with hepatic and renal inadequacy and a high degree of acidity of the urine—a lithemic state. It is my purpose, in concluding, to direct especial attention to this considerable group of cases, since the cause is frequently overlooked and since also treatment is, as a rule, successful if aimed at the etiologic influence. The cough in this form of chronic bronchitis is dry, irritative and attended with slight expectoration. There is nothing peculiar about the physical signs present. The course differs somewhat from that of other forms of the affection in that an exacerbation may occur at any season of the year, depending upon fluctuations in the uricacidemia.

The presence of the preceding causative condition, i. e., the lithemic state of the system, as shown by the high acidity of the urine, diminished renal output, pale stools, large coated tongue, and hepatic enlargement, it is that clinically characterizes this sub-variety of chronic bronchitis. The principles of treatment to be observed are not new; but in order to succeed in the management of these cases the prime requisite is to embrace under the diagnosis a recognition of the cause, so that the line of conduct may be adapted to the lithemic state.

RESULTS AND ADVANTAGES OF CLOSING THE NEPHRORRHAPHY WOUND WITH ASEPTIC ADHESIVE STRIPS.

By AUGUSTIN H. GOELET, M. D.,

of New York

Professor of Gynecology in the New York School of Clinical Medicine
etc

Estheticism is not always considered in estimating the result of surgical work, yet every surgeon must realize that, to some, an unsightly scar is very objectionable, though its location may be one not exposed to public view. Apart from this a neat cicatrix is evidence of neat painstaking surgical work and is always creditable.

In addition to the avoidance of an unsightly scar the use of aseptic Z. O. adhesive strips as recommended by Howard Lilienthal, possesses other advantages.

By avoiding sutures that penetrate the skin in closing wounds means the avoidance of stitch abscesses and a quicker convalescence. Even when perfectly aseptic suture material is employed, infection of the suture track may result from drawing the sutures through the skin. Though the surface of the skin may be rendered aseptic, the deeper layers harbor germs that may become dislodged and dragged through by the sutures.

The time saved by using adhesive strips instead of sutures and the fact that they do not constrict the underlying structures and cut off the circulation as do sutures is a not unimportant item, and is sufficient to recommend them for universal adoption, when they can be employed, independently of the other advantages enumerated.

It is essential that the adhesive strips be sterile or the margins of the wound covered by the strips will become infected and primary union will not be obtained.

FIGURE 1.

The accompanying illustrations show, Fig. 1, the appearance of the nephorrhaphy wound, closed by adhesive strips, immediately after the operation is finished. At the upper angle of the wound above the adhesive strips is seen the gauze strip over which the sustaining sutures for the kidney are tied, and below the end of the gauze drain

projecting from the lower angle of the wound. The adhesive strips are applied, as shown, with space between, and not edge to edge or overlapping, so as to allow drainage for oozing from the margins of the wound.

FIGURE 2.

Fig 2 is a photograph of another case one week after operation upon removal of the first dressing, and shows how well the adhesive strips remain in position and firmly adherent to the skin though they have been saturated with oozing from the wound.

FIGURE 3.

Fig. 3 shows the appearance of the wound in another case immediately after removal of the final dressing three weeks after operation. It will be observed that the marking of the skin from the adhesive strips is more distinct than the line of cicatrix. These will of course disappear.

The result of fixation of the kidney for prolapse will be satisfactory if it is held immovably against the muscles of the back until it becomes adherent by sutures so inserted that they will not tear out when tied (see technique of the method of inserting these sutures further on) and if ordinary care is observed afterwards to avoid strains of any kind that would tend to force the liver down upon

the kidney and loosen the attachment. And it might be added, if the operation is not so long delayed that the kidney structure with its fibrous capsule has become so softened by long continued congestion that no form of suture will hold.

Early operation then is one very important essential for success.

Prolapsed kidney may be suspected when any of the following symptoms are present, viz.:

1. Chronic digestive disturbances; such as gastric irritability, persistent intestinal distention, repeated bilious attacks, etc.

2. Nervousness, restlessness and insomnia, without other ascertainable cause.

3. Unusual fatigue on exertion; particularly after standing or walking.

4. Palpitation of the heart and sometimes vertigo or syncope.

5. Epigastric pain, to the left of the median line, or pain over the region of the heart.

6. Dragging pains in the loin, extending to the groin and down the thigh, aggravated by long standing or walking, which is usually relieved by assuming the recumbent position.

7. Inability to rest comfortably or sleep on the left side, because the right kidney, which is most often prolapsed, drags towards the opposite side out of position when the sustaining pressure of the abdominal contents is removed by gravitating to the opposite side.

8. Irritability of the bladder, more pronounced during the day or after standing or walking. This usually disappears (though not always) after resting for a time in the recumbent position.

9. Jaundice which is transient and intermittent; due perhaps to temporary obstruction of the common bile duct from traction upon the duodenum and head of the pancreas and interference with the return circulation through the superior mesenteric vein.

10. Pain and tenderness over the region of the appendix, simulating chronic appendicitis; and tenderness upon pressure along the course of the ascending colon.

11. Pain in the right ovarian region, which is sometimes misleading in the absence of other symptoms directing attention to the kidney.

12. Acute attacks of pain resembling renal colic. These attacks, which are fortunately infrequent, are no doubt due to obstruction of the ureter from flexure upon itself or kinking as the kidney drags down, or from pressure upon the ureter by accumulation of feces or gas in the ascending colon.

Look for prolapsed kidney in every gynecological patient, whether they have symptoms directing attention to the kidney or not. It will be found in 25 out of every 100 women taken at random.

To detect prolapsed kidney stand the patient erect against a firm table or the wall with the clothing loosened about the waist. Grasp the right loin with the left hand, (sitting in front of the patient) the fingers behind and the thumb in front on a level with the lower border of the lowest rib in front. Direct her to take a deep inspiration and to cough forcibly when she has reached the limit; then to take another deep inspiration and as she expires

press the thumb deeply up under the rib, thus narrowing the space between the fingers behind and the thumb in front, so the kidney cannot pass between them without being detected when the attempt is made to replace it by pressure from below with the other hand. With the fingers of the right hand held firmly together palpate the abdomen to the right of the median line below the thumb of the left hand still held firmly depressed under the rib. If the kidney is displaced below the thumb, it can be engaged between the palpating fingers of the right hand below and the thumb above and outlined, and firm upward pressure will cause the kidney to glide under the thumb up into position. Bending of the body forward upon the pelvis fixed against the table or wall will secure relaxation of the abdominal wall and facilitate the manipulation.

If the kidney cannot be positively or satisfactorily made out in this manner let the patient lie down on her back and manipulate the abdomen so as to replace the kidney if it is down; then grasp the loin with the left hand as described above and let the patient get on her feet while the grasp is retained upon the loin. If now she is directed to take a deep inspiration slowly and to cough, if necessary, if the grasp on the loin is sufficiently maintained the kidney can be felt distinctly as it is forced down against the fingers and thumb and slips between them.

If the kidney is not sufficiently movable to become prolapsed it can be felt by this latter manœuvre, as it is depressed against the thumb on deep inspiration, and recedes upon expiration. If the kidney is not depressed against the thumb by deep inspiration, it is prolapsed and must be found below it. The normally placed kidney can be felt thus, unless the subject is very fat or the abdomen is unusually distended. A prolapsed kidney is not readily detected except by one who has become expert by constant practice unless the conditions are favorable; that is, the abdominal wall is thin or relaxed and pliable. But the method of palpation described above makes its detection much easier than by the methods usually employed; so much easier in fact that by comparison they are valueless. Yet when the prolapsed kidney cannot be made out distinctly by one method others should be tried in turn.

If the colon is distended it will interfere with satisfactory palpation and detection of the prolapsed kidney. This difficulty can be overcome, however, by giving a stimulating enema that will distend the whole colon and let it be expelled.

If the abdomen is unduly rigid or sensitive, dismiss the patient with instruction to rest up and examine her again a few days later, when the soreness has subsided.

There is no form of abdominal support that will keep the kidney in place or support it satisfactorily. All that such support can possibly do is to press upon the ascending colon and through it upon the kidney, and by this means prevent the kidney, perhaps, under favorable conditions from prolapsing to the extreme limit. This will sometimes relieve the most urgent symptoms temporarily. But the variability and uncertainty of such support can be readily appreciated.

The only method of cure is to fix the kidney in place by temporary sutures to the muscles of the back until it becomes adherent.

The technique of the operation is briefly as follows:

The surface of the back where the incision is to be made must be prepared with the greatest care to secure perfect asepsis of the skin. To this end it should be scrubbed thoroughly with brush or pad of gauze and Synol soap, and rinsed with sterile water.

The incision is made parallel to the spine, from three to four inches from it (according to the breadth of the back) on a level with the outer boarder of the erector spinae muscle, from just below the last rib down for about three inches. This incision is made through the skin and fat down to the superficial fascia covering the muscles of the back. This fascia is divided with scissors to the extent of the incision, and the successive layers of muscles are separated in the direction of their fibres and held apart by retractors. When the lumbar fascia is reached, it is divided if it cannot be readily separated from the muscles without doing so. Under this will be found the fat surrounding the kidney or its fatty capsule. This is drawn down and opened high up near the upper angle of the wound. Two fingers are inserted, the kidney located and freed of adhesion to its fatty capsule and brought up into the wound.

If the patient is placed on the table on her side with a deep, wedge-shaped pad under the opposite side the kidney will be found up in position when the fatty capsule is opened.

FIGURE 1.

The sustaining sutures, of which there are two, are inserted in the following manner on the lower third of the exposed surface of the kidney, viz.: A small, curved, round-pointed needle, with the suture (silk-worm gut) threaded directly into it, is inserted, first on the lateral portion of the exposed surface from above downward, taking in about half an inch and penetrating about a quarter of an inch

beneath the surface, in a direction somewhat oblique to its long axis; then it is inserted deeply through the kidney structure transversely, and again superficially on the opposite lateral face from below upward. The second suture is inserted in the same manner just above the first. But if there is not sufficient room, the second suture is introduced, as shown in the diagram (Fig. 4), with two lateral insertions only, leaving a considerable loop of suture upon the outside of the fibrous capsule. It has been found that this latter method of applying the suture will sustain even more strain without tearing than the other, and when the kidney structure is unusually soft and pliable both sutures are inserted in this manner.

The ends of these sutures (the upper one first) are threaded into a large curved needle and carried from within the fatty capsule through the muscles of the loin out upon the skin on each side at the extreme upper angle of the wound and about a third of an inch from the margins of the wound.

The redundant edges of the fatty capsule are trimmed off on a level with the bottom of the wound so as to permit the kidney to be drawn up against the muscles when the sustaining sutures are tied.

The sustaining sutures are tied over a fold of several thicknesses of gauze to protect the margins of the wound and prevent them from cutting into the skin (see Figs. 1 and 2). This fold of gauze must be of sufficient width to cover completely the surface between the suture ends as they emerge through the skin. The tying of these sutures brings the kidney up under the ribs and holds it against the muscular structure of the back so it may become adherent.

To lessen the strain on the sustaining sutures and to drain the wound, gauze is packed around and under the lower pole of the kidney and the end is brought out at the lower angle of the wound (see Figs. 1 and 2).

Sutures are not required for approximating the muscles of the back in closing the wound. As they have not been divided they fall together when the retractors are removed; but I usually insert two or three interrupted sutures of catgut to approximate the margins of the lumbar fascia.

It is seldom necessary to apply ligatures to vessels in the wound as they are drawn aside in separating the muscles and are not wounded. Bleeding points, if found, however, should be controlled by forcepressure and, if necessary ligature before the wound is closed. Oozing is controlled by free irrigation with hot salt solution before the gauze is inserted.

The surface of the skin is cleansed thoroughly of blood and wiped dry, and the margins of the wound are carefully approximated by the assistant while the adhesive strips, a quarter of an inch wide, are applied with spaces between them as shown in Fig. 1.

The wound is then plentifully covered with loose gauze and absorbent cotton held in place by a bandage encircling the body.

This dressing is not to be removed for a week, unless it is saturated by oozing from the wound

when it is renewed for another week without disturbing the adhesive strips.

The gauze drain at the lower angle of the wound is carefully withdrawn on the third or fourth day, lifting up the dressing for this purpose and replacing it afterwards. The opening at the lower angle remaining after removing the gauze drain may be closed with one or two additional adhesive strips of the same width as first applied.

At the end of two weeks the sutures are removed but the adhesive strips need not be removed for another week when all the dressings may be removed and the patient permitted to get up.

During this period of confinement in bed (three weeks) the patient must be kept rigidly on her back, or she may be permitted to turn on the side of the sutured kidney, but must not turn on the opposite side, as that would cause the kidney to drag on the sutures.

MULTIPLE PRIMARY NEOPLASMS IN ONE INDIVIDUAL, (SPINDLE-CELL SARCOMA OF FORE-ARM, ADENO-CARCINOMA OF PYLORUS, MYOMATA OF STOMACH-WALL). TREATMENT WITH COLEY'S MIXTURE.

By ALDRED SCOTT WARTHIN, M. D., Ph. D.,
of Ann Arbor, Michigan.

Assistant Professor of Pathology, University of Michigan.

According to a recent paper by H. Gideon Wells (*Jour. of Path. and Bact.*, June, 1901) only seventeen cases of the simultaneous appearance of sarcoma and carcinoma in the same individual have been reported. The case to be described below will add one more to this number, at the same time being of interest as having been treated with Coley's mixture of the toxins of erysipelas and bacillus prodigiosus, and because of the possible relation of certain of the pathological findings to this treatment. The case came from the surgical clinic of Dr. Nancrede, and the clinical features will be more fully presented in another paper by Dr. George, a member of the surgical staff. In this report I shall consider more especially the pathological aspects of the case.

History.—Mr. S. A. W., farmer, of the age of 73, was admitted to the University Hospital, December 13th, 1900, for treatment of a tumor on the inner side of right fore-arm. His family history was negative. He was born with congenital amputation of left hand at the metacarpophalangeal articulations. He had the usual diseases of childhood, an attack of gonorrhea at 20, and at 30 years of age a severe attack of 'erysipelas' by which he lost his right eye. In May, 1900, he noticed a small lump beneath the skin of his right fore-arm, about half way between elbow and wrist. This was freely movable over the underlying structures. The growth increased in size, at the time of admittance to the hospital being about the size of a hen's egg, slightly nodular, and hard and elastic. It was movable upon, but adherent to the deeper structures. The skin over the tumor was adherent, cyanotic and mottled reddish brown. There was infiltration of the neighboring tissues. No evidences of metastases were present, the axillary glands were not enlarged. The clinical diagnosis of sarcoma was confirmed by the examination made in the pathological laboratory of a small excised portion which showed the structure of a large spindle-cell sarcoma.

The case being considered hopeless, a radical operation being strongly contra-indicated, it was decided to try the effect of injections of Coley's mixture into the tumor. This treatment was begun on December 21st, by an injection of $\frac{1}{2}$ minim. This amount was increased $\frac{1}{2}$ minim

every day or every other day, according to the severity of the reaction. After each injection, usually within half an hour, the patient had a chill and a rise of temperature. At the point of injection there was a painful, reddened area; later a whitish discharge and slough. In spite of the large areas of necrosis produced in the growth by this treatment it grew with great rapidity, and soon infiltrated the entire fore-arm. The axillary glands also became enlarged and later showed fluctuation. An incision in the axilla permitted the escape of a large amount of creamy pus-like material. The utility of the treatment being very evident, it was discontinued on the 1st of February, 1901. The patient's general condition became rapidly worse, and death occurred on March 6th at 10 P. M. The autopsy was performed by me at 9 A. M. of the next day.

The laboratory protocol is condensed as follows:

Body well built; bones large. Thorax barrel shaped; abdomen below level of ribs. Congenital amputation of left hand at metacarpophalangeal articulation. Fingers represented by tubercles having calloused tips but no nails. Musculature good; rigor mortis is present throughout. Skin is pale. Large amount of panniculus; slight edema over the lower extremities. Body heat present over liver region.

On the outer aspect of right ulna there is a large fungoid tumor covering the lower two-thirds of the fore-arm. The growth is irregularly nodular. In its central portion there is a deep cavity $2\frac{1}{2}$ inches long by $1\frac{1}{2}$ broad. The floor of this deep ulcer is covered with a thick pus-like material. The remaining portion of the growth is covered with a dry scab; about this there is an area of deeply pigmented skin and many enlarged veins. The growth is firmly attached to the radius, moving only with the bone. Its consistence is fairly firm except around the ulcer. The skin over the remaining portion of fore-arm is tense, scaly and shining; in the subcutaneous tissue there are a number of small scattered nodules which are freely movable under the skin. On section the tumor is found to be attached to the periosteum of the radius, completely surrounding this bone and filling up the space between the ulna and radius. The muscles of the fore-arm are almost entirely replaced by the growth, the tendons are preserved and are completely surrounded by the tumor. The cut surface of the tumor is mottled white and red, its consistency rather firm, yielding but a small amount of cells on scraping. Soft cheesy areas are found all through the growth, most numerous about the ulcer. The small nodules beneath the skin present an appearance similar to that of the main tumor.

The meninges are thickened, and the subarchnoidal fluid greatly increased in amount. The circle of Willis shows an advanced stage of arterio-sclerosis; in the cerebral branches are a number of saccular aneurysmal dilations. The carotids, especially the left, are markedly sclerotic, and are widely dilated. Attached to the vessel wall at the point of division of the left anterior and middle cerebral arteries there is a recent mixed thrombus extending into the left middle cerebral but not completely obliterating it. The left occipital lobe is atrophic; on section shows areas of sclerosis and small cysts filled with clear fluid. The brain as a whole is very anemic and shows marked edema. (The spinal cord was not examined.)

The examination of the mouth, upper respiratory tract and neck organs is negative.

Pleurae of the left lung adherent all over; on the right adherent only posteriorly at the base. Both lungs are voluminous, mottled red in color, moderately anthracosed, and on section yield an abundant foamy exudate. A large tendinous spot is present on the posterior wall of right ventricle, a smaller one on the anterior wall of left auricle. Subpericardial fat is greatly increased. Heart muscle is pale yellowish brown in color, very soft and tears easily. The ventricular wall is 20-25 mms. thick; in it are a number of small fibroid areas. Papillary muscles are hypertrophic. Mitral flaps thickened; aortic orifice admits of index finger, its flaps are stiff and rigid, a ring of calcification extending around the orifice. The flaps are adequate. Tricuspid orifice admits four fingers, the right ventricle is dilated. The coronary arteries show advanced sclerosis, in the anterior branch of the left is a partly organized thrombus. The arch and descending aorta show advanced sclerosis and fatty degeneration of the intima.

The omentum is very rich in fat, and is rolled up, lying between the surface of the liver and the abdominal wall.

It is firmly adherent around the gall-bladder. The intestines are collapsed with the exception of the cecum. Between the coils are a number of old vascularized adhesions.

The spleen is small, pale bluish red, and of soft consistency.

The adrenals present no abnormal appearances.

Both kidneys present practically the same appearance. The fatty capsule is very thick. The fibrous capsule is also thickened but strips off very easily. The surface is granular, containing numerous small cysts filled with clear fluid. The kidney parenchyma is decreased in amount. The outlines of the medullary rays and labyrinth are distinct; the labyrinths are swollen, cloudy and yellowish in color. Pelvic fat is in great excess.

The examination of ureters and bladder is negative.

The stomach is dilated, filled with grayish yeasty-smelling fluid containing food remains. The mucosa is atrophic. Near the cardiac orifice there is a small polypoid growth in the mucosa. The pyloric opening is free. The mucosa in the pyloric portion is greatly thickened, presenting many polypoid growths which are largest just above the pyloric ring. These growths show no evidences of ulceration. In the serous coat of the stomach, both anteriorly and posteriorly there are a number of small whitish, firm nodules about the size of a pea to that of a cherry, apparently arising from the muscular coat.

The examination of small and large intestine and rectum is negative.

The liver is small, its capsule thickened. On section it is very pale and cloudy, the outlines of the lobules indistinct. The cut surface is very smooth, almost homogeneous, consistence firm. The gall-bladder is retracted beneath the liver edge, is hour-glass in shape. Its walls are greatly thickened. The small cavity contains 15 brown and black calculi, the largest the size of a cherry, and a small quantity of orange-colored fluid. The cystic duct is obliterated; the common duct is patent, its lumen greatly dilated containing golden-brown bile.

The pancreas is surrounded by a thick layer of fat. The section shows atrophic lobules with marked fatty infiltration. The blood-vessels are markedly sclerotic.

The mesenteric and retroperitoneal glands are apparently normal. The abdominal aorta shows a high degree of sclerosis and fatty degeneration of its intima. In the left iliac and femoral veins there are recent thrombi. In the right internal iliac artery there is an organizing thrombus partly obliterating its lumen.

Both testicles show advanced atrophy and fibroid change. The prostate is enlarged, on section shows numerous small nodules.

The voluntary muscles are yellowish, softened, tear very easily, and have a distinct fatty shine.

The glands in the right axilla are replaced by a nodular growth about the size of a normal kidney. On section this presents an appearance similar to the primary growth in the forearm, but of softer consistence.

Microscopical Examination.—Sections of the primary growth in the forearm show it to be a large spindle-cell sarcoma containing many large polymorphous cells and having but little intercellular substance. At the points of the injections into the growth there are large areas of soft cheesy necrosis. No leukocyte infiltration is found either about these or about the superficial ulcer. Remains of striped muscle and tendon occur throughout the growth. The axillary tumor has the same structure as the primary; in it there are also large areas of soft cheesy necrosis.

The polypoid growth in the pylorus has the structure of an adenoma infiltrating the submucosa and muscularis (adeno-carcinoma). The polyp from the cardiac end is an adenoma showing no infiltration of the stomach wall. The small nodules taken from the serous coat of the stomach are formed of irregular bundles of unstriped muscle and connective tissue (leiomyo-fibroma). The sections of the stomach mucosa show a chronic catarrhal gastritis.

The lung is atrophic, moderately emphysematous, its vessels congested and there is marked edema. The spleen is also atrophic, moderately congested and its small arteries very sclerotic. The kidneys show an early stage of arterio-sclerotic interstitial nephritis with a cloudy swelling and fatty degeneration of the cells of the convoluted tubules. The adrenals show no change.

The liver is atrophic, the central vein congested. The liver-cells show cloudy swelling and fatty degeneration.

Sections of the gall-bladder wall show a chronic cholecystitis. The pancreas shows an extensive atrophy with fatty infiltration. The capillaries of the areas of Langerhans shows a high degree of sclerosis, many of the areas resembling hyaline kidney glomeruli.

The heart muscle and also the voluntary muscles show extensive fatty infiltration and degeneration. The lymph-glands are atrophic and contain large masses of hyalin. No hemolymph glands were found in the retroperitoneal region, but two from the cervical region show atrophy and pigmentation. The parathyroids are larger than normal and show fatty infiltration. The prostate shows a granular hyperplasia.

Pathological Diagnosis.—Primary Spindle-cell Sarcoma of right forearm, metastasis in right axillary glands; Primary Adeno-carcinoma of Pylorus; Adenomatous Polyp of Cardiac Portion; Multiple Myomata of Stomach Wall; Thrombosis of Left Anterior and Middle Cerebral and Right Iliac Arteries and Left Iliac and Femoral Veins; Arterio-sclerosis and Fatty Degeneration of the Intima of Large Arteries; Aortic Stenosis; Cardiac Hypertrophy and Dilatation; Atrophy and Parenchymatous Degeneration of All Organs; Early Stage Interstitial Nephritis; Chronic Catarrhal Gastritis; Cholecystitis and Cholelithiasis; Sclerosis of the Areas of Langerhans; Atrophy of Right Optic Nerve and Left Occipital Lobe. Congenital Amputation.

The occurrence of multiple primary neoplasms is so rare that the case described above can be regarded only as an interesting pathological curiosity. The combination of carcinoma and sarcoma is so infrequent that it must be looked upon only as a mere coincidence. There is no evidence to explain this rarity of occurrence on the hypothesis that the presence of one malignant tumor is unfavorable to the development of another. If malignant growths are caused by parasites it would be expected that multiple growths would occur frequently; the rarity of such event has therefore been used as an argument against the parasitic nature of malignant neoplasms.

Of more immediate practical interest are the pathological changes in the sarcoma and in the organism as a whole which may have some connection with the toxin treatment. At the point of the injections there were large areas of necrosis. No leukocyte infiltration was present about any of these areas. The fatty degeneration of the intima of the blood-vessels, heart, voluntary muscles, and the parenchymatous changes in the liver and kidneys are to be explained as caused by systemic intoxication. This may have arisen either from the absorption of poisons from the necrotic portions of the sarcoma or from the injections of the toxins. The marked reaction after each injection gave evidence of the systemic effects produced by these. Coincident with this treatment arose the rapid development of general cachexia, involvement of the kidneys, multiple cachectic thrombosis, etc. The part which the stomach carcinoma played in the development of these conditions was probably very slight, as it gave rise to no symptoms. There was no obstruction of the pylorus, no ulceration, and the tumor could not have been diagnosed clinically.

The direct effect of the injections of the toxins into the sarcoma was the production of a large area of necrosis of the tumor-cells about the point of injection. After each injection there were evidences of systemic intoxication, as shown by the marked reaction following the treatments. The toxins act as protoplasmic poisons, killing the tumor-cells with which they come in contact. Any decrease in the size of a tumor so treated is due only to the death of portions of its substance, and its complete

disappearance would depend upon an excess of this destruction over that of the cell-growth of the tumor. There is no evidence that the toxins have any specific action upon the cells of tumors. The same phenomena of cell-destruction may be produced by many other protoplasmic poisons.

If the spontaneous necrosis and degeneration which occurs so frequently in malignant tumors is to be regarded as one of the factors in the production of tumor-cachexia, the excessive necrosis produced by injections of toxins must be favorable to the rapid development of cachexia. To the effects of the absorption of products from the dead tumor areas must be added also the systemic effects of the substances injected. These are undoubtedly absorbed, to a certain extent at least, and produce effects other than purely local ones. The destruction of a tumor by such means is therefore attended by the danger of systemic intoxication and the more rapid development of cachexia. There is also the possibility that injections of large size favor metastasis by mechanically loosening the cells of the tumor into the lymph stream. The autopsy findings in this case suggest the occurrence of such results of the toxin treatment.

ARE THE SMALLER MEDICAL COLLEGES AN ESSENTIAL FACTOR IN MEDICAL EDUCATION.*

By WILLIAM J. GILLETTE, M. D.,

of Toledo, Ohio.

Professor of Abdominal Surgery and Gynecology, Toledo Medical College,
Surgeon to Robinson Hospital.

The subject of medical instruction has been a fruitful theme for discussion from the earliest inception of medical colleges in America. That it has borne fruit of great value is a fact patent to all. During the past decade the improvement in medical teaching has been most marked, and has kept pace with the rapid improvement in medicine itself—indeed, the one has been the necessary sequence of the other.

Within the memory of all present, but few schools made any special requirements as to literary qualifications, a condition precedent to matriculation. As a result, many gained admission in such an unprepared condition as to reflect no credit on themselves, and less on the institution whose doors were open to them. The course of instruction was short in the extreme, but two terms of five months each, often less; and consisted almost entirely of didactic lectures upon what might be called the seven elementary branches; clinical and laboratory work being an unknown quantity. As a result, of constant agitation by the better educated portion of the profession at large, with, I am sure, the hearty approval of the teachers, in a vast majority of cases, in the different medical colleges in the country, a radical change has been brought about.

I am aware that critics upon this subject have been, and are yet, inclined to blame the colleges for lack of interest along these lines; unmindful of the fact that teachers lecture to just such stu-

dents as are furnished them and recommended by the physicians themselves. If the general practitioner had long ago insisted upon taking into his office as a student, only such as he was satisfied had, by preliminary education and fitness, qualified himself for the study of a profession, the change so slowly wrought would have come long ago. But slow as it may have been, by a process of evolution, the modern medical college has come into existence. To my mind the most important change, because the most far-reaching in its results, is the higher standard of literary qualifications required by all colleges that make any pretense to thoroughness. A high school diploma, representing four years of study, is alike creditable to the student and the college that receives him. True, a degree from a literary college, earned after four additional years of study, is better; and may at some time in the future be demanded by all.

The highest ideal of the physician is but too seldom reached, and then only by degrees and not at a single bound. New standards, brought about by the greater demands of the new century, make a higher degree of general culture and more exact technical knowledge in the physician absolutely imperative. Many of the states have enacted laws, stating in specific terms, the preliminary education which the would-be candidate for the degree of the doctorate shall possess. The course of instruction in medical colleges has been lengthened to four years of at least six months each, and I am of the opinion that in the near future all will demand four years of nine months each.

Laboratory work during the first two years is now compulsory and a prominent feature; reserving clinical and didactic lectures for the last two years of student work. I do not believe the former will ever entirely supersede the latter, nor do I deem such a course wise.

In a utilitarian age like the present, when concentration in every department of human endeavor seems to pervade the atmosphere as it has never done before, the question may well be asked in a meeting like this, is it to extend to the schools of learning and is the so-called smaller medical college to go, and give place to a limited number of larger ones connected with universities and located in the great centres of population?

In the discussion of this subject of medical education and training, there seems to be a spirit among certain of the profession decrying the smaller medical schools of the country; but the picture they draw of them is, in my opinion, of entirely too pessimistic a character. "By their fruits ye shall know them," and as often as not it has been the graduates of these same colleges in whom culture and attainment have been eventually developed in the highest degree. Many of them could be named who have become the great masters of American medicine, who have been the great pioneers. No country on earth has furnished the number of men who have entered and mapped out so many new fields of medicine into which men of other countries have followed and assisted in cultivating. It has been said with a great degree of truth, I think, that independent and original thought and investigation leading to discovery, are indigenous to American

*Read before the Pan American Medical Congress at its meeting in Havana.

soil. After all, as Carlyle has said: "It is not thy works which are all mortal, infinitely little, and the greatest no greater than the least, but only the spirit thou workest in that can have worth or continuance." Now this spirit of work and enthusiasm can be found developed in a small school as well as in a large one. Indeed, I am not sure but that it is as often found in the one as the other.

A great medical teacher and writer, whom all American physicians, and I think I may say, all wherever medicine is known, delight to honor, in a paper half apologetic for his American confreres and colleges, read at the recent International Medical Congress in Paris, uses the following language: "Medical teaching, however, will be better and more uniform, and more in accord with the requirements of the people, when our one hundred and fifty-six schools will have been reduced to twenty-five, and each of them will be connected with a university as its medical department." In other words, the medical colleges outside the cities of Boston, New York, Philadelphia, Baltimore, Buffalo, Chicago, San Francisco, and possibly New Orleans, which are not connected with a university, whose graduates in civil and military life have added lustre to American medicine and dignity to the commonwealth, are to have no part in the training of American youth who may seek admission to the ranks of our profession. I would not, were it in my power, detract in the least degree from the well-earned fame these great centres of learning have long enjoyed, because of the gathering together of such master intellects as have given them place and power; but, is it not possible for those, not members of these faculties, to do good work? Men make schools—schools do not make men. The time has long since gone by when a man's geographical location can be considered an index of his capabilities or qualifications. The college, large or small, but lays the foundation, the superstructure, whatever it may be, depends upon the individual himself. No medical college ever did or ever will, make a complete physician, nor can we really ever have a finished product, for one of the unalterable laws of nature decrees that man must grow or deteriorate: there is no standing still.

Many of the smaller schools are doing most excellent work. While there may not be that repetition or multiplicity of material that enters into the formation of a well-regulated and equipped laboratory, still all the essentials are there, all that can be used with profit, and those of the very best at that. In bacteriology, every step in the process of germ cultivation, from the preparation of the culture media, through every gradation of planting, growth, mounting and staining, together with careful examination with the best of microscopes, the student is thoroughly trained. Verification of the germ in the guinea pig follows, that nothing may be omitted. The work in chemistry, histology and pathology is carefully taught by teachers, who, enthusiastic themselves, inspire the same enthusiasm in their students. The same may be said of the work in the anatomical department.

To my mind, the subjects most neglected in all schools are *Materia Medica* and *Therapeutics*. The application of remedies to the treatment of dis-

eased conditions is a matter of prime importance:—it has a dual interest—one to patient, the other to physician. Teachers give with the most minute detail the etiology and pathology of a disease, and dismiss with a few glittering generalities the treatment. As a result, there is growing up among us a class of medical nihilists who think drugs well nigh useless. It has been said by some one that "it does not matter so much what you give as who gives it." From a commercial point of view this may be correct; but from the scientific standpoint it is lacking in every element of truth. From the latter view point it does matter who prescribes; it is easy to tell then what will be prescribed—it will be the remedy indicated at the particular time and in the concrete case. It will not be the physician who will turn to his shelves, where are arrayed an assortment of bottles variously labelled: "Rheumatic cure," "Cough mixture," "Heart tonic," "Mixed treatment" and the like. One may well ask the question: "Has prescribing become a lost art?"

In the matter of clinics it is not so much the amount of material, the multiplicity of cases seen, as the care and thoroughness given to each individual case. A few patients, carefully studied in every detail and phase of development, and watched from the inception of the disease to the final restoration of the individual to health, are of more practical value to the student than a dozen looked at through opera glasses from the top row of the amphitheatre.

Small schools, as well as large, take their students into the wards of the hospitals, where they are allowed to see and examine the patients, ask questions upon any or all phases or complications of the disease. Moreover, the case being constantly before the student, he becomes familiar with the appearance of the patient at different stages of the disease, and results of the various forms of treatment are noted and carefully weighed. In small schools each student receives a greater amount of individual attention and assistance in the formation of habits of self-reliance and investigation which are invaluable. Personal contact of pupil and teacher is a matter of no small importance.

In conclusion, my plea is not for the destruction of any of the schools of worth we now have, but for a recognition of merit wherever found, whether the college be large or small; for a higher standard of excellence in both, to the end that American Medical colleges and their graduates may be recognized as they can be and will be—the peers of any in the world.

Glandular Fever.—A. Guérin discusses glandular fever in the *Journal de Médecine de Bordeaux*, (June 30, 1901). Fever and enlarged glands exist for a few days only; then the fever disappeared, while the glands remained enlarged for a variable length of time. The submaxillary glands, those at the angle of the jaw, and the cervical glands may be involved, singly or all together. Guérin reports two brothers, in one of whom nephritis existed, in the other glandular fever, at the same time and from the same causes. He also reports two other cases, in a grandmother and her grandson. In the former typical glandular fever occurred. In the latter a tonsillitis. Other similar cases were found in the literature. Guérin believes that glandular fever is polymorphous. He suggests that it is but one of the many manifestations of influenza. [M. O.]

The Plague Situation in California.—The State Board of Health of California has just gone on record again on the plague question. In a report issued by it the statement is made that "it is significant in this connection that the latest case of bubonic plague alleged to have been discovered in this city was on April 8th, the day before the State Board commenced its active investigations. After that date no case was discovered, although many were asserted to be such, until an autopsy disproved the assertion." This remarkable announcement comes unsupported by any statement as to who made the autopsies, and what the cause of death was in the cases alluded to; and in spite of the publication in the *Public Health Reports* of October 11th, of the cases of plague with attending fatalities from July 6th to September 27th inclusive. By reference to the table in that report it will be seen that in the period mentioned ten cases of plague occurred with a known mortality of seven, the termination of one case (September 20th) being unrecorded.

The whole controversy, from its beginning more than a year ago, would be amusing if less were at stake. It reminds one of the extravagances of opera bouffe. Just what the State Board hopes to accomplish by this extraordinary announcement is not easy to perceive. From the beginning its utterances have been discredited. They represented opinions and not views based upon actual investigation of those dead of the strange disease. That any one not immediately under the Board's influence will accept the equally gross misstatements in its latest report is beyond belief.

The matter of real moment to California is whether other States will be assured that State officers hostile to the truth will deal adequately with a grave situation and use every available means to prevent the spread of the pest outside the State's borders. What we urge again is that by intelligent and willing action the authorities of California use every endeavor to suppress a plague that menaces the public health of the country, and imposes a heavy international responsibility. What kind of altruism, we should like to inquire, is this

that assumes indifference to its own life—a fatalism difficult to accept—and an equal indifference for the lives of others? Moreover, can a purblind State be trusted to preserve the health of a community and to eradicate an existing pest center?

We may say, and we believe we have many sympathizers, that we are tired of the plague controversy. There is indeed no matter for disagreement; plague has existed for almost two years in San Francisco, and its prevalence has not only been demonstrated beyond dispute, but that it prevails in the Chinese quarter of the city is the conviction of every intelligent person who has taken the trouble to examine into the matter.

If the State of California persists in its foolish practice of prevarication it may suddenly discover that other States have wearied of the pastime. What its feelings will be, should the severe penalty of isolation by quarantine be invoked, can readily be conjectured. And yet, even so drastic a measure might not only be justifiable, but prove to be the only one capable of bringing the defiant and resistant State authorities to a full realization of the consequences of equivocation.

Some Successful Tumor Transplantations.—The subject of the transplantation of tumors is one that has excited the interest of clinicians and pathologists for several years. The number of positive results has been astonishingly small. In a few instances successful transplantations have been made in animals, and in two cases in human beings, but in these the subject of the experiment furnished both the tumors and the site of inoculation. Recently Loeb, of Chicago, has made a valuable contribution to this subject (*Journal of Medical Research*, July, 1901), commencing by transplanting the fragments of a carcinoma of a cow, and a carcinoma of a mouse into animals of the same species. His results were entirely negative. Later he commenced a series of consecutive transplantations of a sarcoma of the thyroid gland of a white rat. The original tumor was a cystic sarcoma, the cysts being produced by a gelatinous softening of the tumor cells, and, as the remaining cells arranged

themselves in a sort of epithelial-like line around the walls of the cyst, we may assume that it belonged to the group of angio-sarcomas, a tumor that by many is regarded as of endothelial origin. This tumor was extirpated, recurred locally, and gave a local metastasis. The animal died of an operation. Fragments of these tumors were transplanted in the subcutaneous tissue, or into the peritoneal cavities of other rats, and examined at varying periods in order to determine the changes that ensued. Usually the fragments became at first necrotic, many of the nuclei, however, remained vesicular; but in a short time it was possible to distinguish them from the nuclei of the connective tissue cells. Finally, some of the cells in the midst of the lesion began to show cario-kinetic figures, then most of the connective tissue gradually became transformed into a tumor mass that presented the same cystic arrangement that the original tumor had presented. Nearly always, however, the central portion of these tumor masses was necrotic. Efforts were made to transplant the tumors by feeding them to the animals, and by injecting fluid from the cysts into the peritoneal cavities of other animals. The former experiments were invariably unsuccessful; in a few of the latter positive results were attained. An interesting series of experiments consisted in permitting fragments of silk, cotton or agar to become penetrated by the tumor cells, by placing them in the tumorous tissue, and then transplanting them to other animals, when it was found that the tumors grew from them. Nearly always the tumor would continue to grow while the animal became more anemic and cachectic, and finally died. In some cases, however, the tumor ceased growing, when it was found that incision and transplantation of a portion renewed its activity. During fifteen months in which these experiments were continued, the tumor maintained its original histological character, and its virulence was not altered. It could not be transferred to any animals excepting rats and it was not affected by the action of iodide of potassium.

In considering this paper several points occur to us, some of which evidently occurred to the author also. He speaks of the analogy of some of the histological characteristics of the tumor to the changes produced by the tubercle bacillus. We cannot escape the conviction that in many cases these transmissible tumors, so called, which are found in the lower animals, are not really tumors at all, but are manifestations of some infectious agent that produces an infectious granuloma. It is not necessary to suppose that this is a hitherto undiscovered form of infectious agent, because we know

that certain tumor-like growths are produced by the tubercle bacillus, that do not resemble the ordinary necrotic cheesy area. In fact, in some cases the appearance is so atypical that it has been described as sarcoma, and only inoculation experiments, or staining sections for the tubercle bacilli, has revealed the true nature of the case. It must not be understood that we are attempting to instruct Loeb regarding his tumor. We have not the least doubt that his diagnosis of sarcoma was entirely justified according to the accepted criteria for the diagnosis of tumors. What we wish to suggest, however, is the possibility that many sarcomas are only infectious granulomas that for some reason or other fail to produce focal areas or necrosis. The whole subject of tumor formation is in such a miserably confused and unsatisfactory state, as a result of our inability to discover the cause, that dogmatic statements are entirely out of place.

Report of the Milk Commission of the New York Medical Society.—Considerable interest will be attached to the report just published of the summer work of the Milk Commission appointed by the Medical Society of the County of New York. When it is remembered how universal is the applicability of the results obtained by these scientific workers and how far reaching are the evils resulting from milk-contamination, some idea may be entertained of the value of such an undertaking. Done in the heat of our oppressive summers at much personal inconvenience, and at times in the face of more or less positive opposition, the Commission has arrived at certain data which must be taken as conclusive evidence. Thirty visits were made to farms and dairies, some located one hundred and eighty miles from New York City. Each of these visits consumed at least one day, and some several days, in order to afford thorough investigation of the premises and methods of working. In the work of the Commission the individual farm or dairy and not the milk-company has been regarded as the unit for study and investigation. One interesting and suggestive result obtained was that an elaborate and extensive plant is not necessary to produce a clean milk. The contamination of milk is most marked during the first forty-five minutes, and here is where the largest amount of precaution must be taken. This includes cleanliness in every sense of the word. The udder and adjoining parts must be thoroughly cleaned; the hands and dress of the milker should be sterile, as far as possible; the cans, pails, and strainer must be scrupulously clean; dust and insects from dirty lofts and ceilings must be avoided by the careful use of the brush and whitewash; and immediate immersion of the milk thus drawn in ice-

water at a temperature of 40 degrees F. is most essential to destroy the germs that will gain entrance notwithstanding the utmost care that may be observed.

An examination of the results shown in one specific case will be of interest here. The milking was done in a barn, the ceilings of which as well as the hay in the lofts were covered with dust; the windows were filthy and a southern exposure greatly increased the heat.

Added to these was a filthy manure-gutter, and an accumulation of farming utensils and clothing, full rations for the cows, the presence of swarms of flies necessitating the constant use of the tail and restless moving of the animals, and water of 60 degrees F. in the aerator. Under such adverse conditions the milk tested on the spot showed a bacterial count of 455,000 to the cc. After whitewashing and cleansing the ceiling, washing the windows and floors, and placing green shades to screen the sunlight, thorough disinfection of the manure gutter, the removal of clothing and other material stored in the room, and cleansing of the cows, which were receiving scant rations, and straining of the milk in the dairy and not in the barn, the count showed only 3600 bacteria to the cc.

The suggestions of the Commission are comprised under three heads as follows: 1. Strict cleanliness, which refers to the barn, yards, cows, milkers, and all the utensils. Bacteria which get into the milk by means of dirt are thus thoroughly excluded. 2. Rapid and sufficient cooling of the milk to prevent the development of the germs that do get in. 3. Thorough icing around the milk until it reaches the consumer in order to arrest the production of toxins.

There has probably not been undertaken in recent months a more valuable series of observations than those here noted. The dissemination of disease by contaminated milk is a well-recognized factor in pathology, not only through the direct transmission of germs, but through the action of their toxins as well. The summer complaint of children no doubt could be very materially diminished because of lessened toxin-formations, if milk primarily but weakly infected could be used as a working-basis for the production of infant foods. It is to be sincerely hoped that the work of the Commission so ably begun will be carried on in New York and that similar Commissions will be established in other States. There will thereby be disseminated a better appreciation among farmers and milk-dealers of the value and absolute necessity of sterile methods in the preparation of milk, and from a financial standpoint it will undoubtedly well repay those producers who will assume the small additional cost and labor

that must be incurred in the adoption of such methods.

No Border-Line in Medicine.—International prejudice is never more inappropriately shown or more ungraciously expressed than when it resents the good offices of foreign friends in a time of need. The fact that one of President McKinley's nurses happened to be a citizen of Canada probably did not suggest in the remotest degree to the vast majority of American people a thought of criticism. The prejudice is too microscopically small to be worth even now a moment's notice were it not that it unfortunately found expression in an American medical journal—the last place in which it should have been seen. We print elsewhere the dignified reply of the *Canada Lancet*, and we assure our Canadian contemporary that we are in full accord with the sentiments which it has itself expressed. The American medical profession, moreover, does not regard the Canadian medical profession as "alien." The science of medicine is too cosmopolitan, and the relations between the United States and Canada are too many and close, to tolerate the exhibition of such a petty sectional spirit—a spirit, however, which only harms him by whom it is expressed.

Medicine at the Yale Bi-Centennial.—A celebrated American university, in point of foundation the third oldest in this country, has recently celebrated its bi-centennial. At this celebration, statesmen, jurists and scientists gathered to do honor to their alma mater. Men successful in business and commercial life were there in multitudes. The medical profession was represented by great numbers of alumni, many of them men of the utmost distinction, and medical science was not unrepresented in the ceremony. Professor Welsh's address may be taken as a mark of Yale's recognition of a great profession. At Yale there has been for many years a medical department in the university which has made an honorable record, although it cannot be said that it has impressed itself profoundly upon the university as a whole. The world does not turn naturally to New Haven as to a great medical centre. This is not necessarily because—as is so frequently alleged—Yale is situated in a comparatively small city, for in Germany and Scotland there are most distinguished medical schools, thronged with students, and imparting the best instruction, in towns of a few thousand inhabitants. It is not because the other courses of the university at New Haven overshadow the medical department, for we have the examples of Harvard, of Columbia, of Chicago, and of Pennsylvania, in which medical

schools, parts of the universities they represent, work side by side with the other departments, holding rank of equal eminence. Rather, we think, the fault lies in the tendencies of the medical profession of America. The academic career, so-called, seems to offer insufficient inducements to the ambitious American medical student. He wishes for the glory of a great practice, the power of accumulated wealth, for the amusements of a great city, and particularly for the glamour lent by association with riches or social distinction. And some of these he thinks he cannot obtain in the environment of a single university, or in a small town of which the university forms the most important part. Therefore let the inducement be ever so great from a financial standpoint; let the opportunities for enduring scientific work be ever so alluring, the small towns cannot, or at least do not, attract medical students in America.

It must not be overlooked, however, that the supreme disadvantage under which small university towns labor in this respect lies in the absence of hospital and clinical facilities. The great majority of medical students will instinctively go to the big cities in which are situated the great hospitals, the fame of which has gone abroad. America is a country of big cities, and these have a centripetal power that is well-nigh irresistible for medical students. Cornell University has recognized this fact, and has established her medical school in New York. It is said that Princeton also has been contemplating such a college in some neighboring large city—but this is only rumor.

If we have missed the note of a full medical participation in the Yale Bi-centennial, it may have been because as medical men we naturally were expecting too much. The all-round university idea must include a full recognition of the faculty of physic. While wishing Yale the best of everything, we hope especially that when another hundred years have rolled around, and she is celebrating with increased glory, influence and wealth her tri-centennial, her medical school may not be the least part of the whole.

Peril by Fire.—The disastrous conflagration in this city last week, by which more than twenty persons met death in its most terrifying form, illustrated once more a problem which seems as though it were destined never to be satisfactorily solved. That an eight story building can be erected in the very midst of Philadelphia's most crowded marts, in such a fashion that it can become a mass of flames from cellar to roof in five or six minutes, is a demonstrated fact. The disquieting reflection after

all is that many other just such buildings are still standing, in this and every large city. To the medical mind, intent everywhere upon meeting and controlling all the possible causes of death, this seems to be a mere mechanical problem, and one that does not compare in complexity with the kindred problem presented by the infectious diseases. And yet it is one which is not yet solved by architects, builders and, above all, building inspectors. One might suppose that with all the strictly fire proof material now available for constructing tall buildings, such as steel framework, brickwork, and patent floors, buildings could be put up that would not catch fire so ruthlessly that people would not be able to escape from the fourth story of them with their lives. It will not do to blame the elevator shaft entirely. This shaft acts like a chimney, to be sure, but chimneys do not necessarily set fire to houses, and in a genuinely fire proof building even an elevator-chimney would have nothing to burn. At the recent fire the ambulance and hospital service was conducted perfectly, as is the rule in Philadelphia.

The Psychology of Hereditary Suicide.—An extraordinary family history is recalled by the recent suicide of a farmer named Briggs, in Connecticut. According to the report of the case, as published in the *New York Sun*, this was the twenty-second case of suicide in this family in four generations during a period of fifty years. Lying in suicides' graves in the village cemetery are the great-grandfather, the grandfather, father, brother and two sisters of this latest victim of this remarkable family craze. A curious and significant fact is that the contagion has not been confined in this family to relatives by blood, but in one case at least one of the women who married into the family made away with herself. The report published in the *Sun* gives many gruesome details of the gradual wiping out of this extraordinary family by suicide—but we are not concerned here with details, which, after all, are only a commonplace list of hangings, drownings and shootings. What interests us is the scientific problem involved, for few persons will question that here is a nice problem in heredity, or at least in mental contagion.

We doubt whether there is another record in the world that equals this of the Briggs family. Instances, however, have been reported of epidemic suicide and of suicide among near relatives. The story is well known of the ancient tyrant of Miletus who, in order to stay an epidemic of suicide among the young women of that city, ordered that the body of the next offender should be exposed naked in the market place. This broke the charm, whatever it was, and the self-slaughter ceased. Mabille,

a French writer, reported in 1891 the case of three sisters, who committed suicide within three years. Some years ago we commented in these columns on a case of double suicide, in which two young women, who were close friends, threw themselves from a ferry boat into the Delaware river. These cases of family suicide, or epidemic suicide, or double suicide, or suicide in common, can all be classed under one head; that of *suggestive* suicide. Herein lies the psychological problem; for it seems indubitable that when one person commits suicide from the force of example set by another person, that person is very profoundly under suggestive influence to commit an act which is against the strongest instinct in human nature.

The initiative in such a case has not come from within, but from without; it is not spontaneous, but communicated; not original, but derived. This is the very essence of hypnotic suggestion. In the case of the two young women there was a mutual suggestive influence; in the case of the Briggs family there has been an hereditary one. In medical jurisprudence a fine but critical point occurs as to the degree of guilt that attaches to a survivor in a case of attempted double suicide in which only one of the parties perishes. Some lawyers maintain that this survivor can be held for homicide, in having compassed the death of the other.

Lorin L. Lewis, Esq., of Buffalo, N. Y., one of the counsel appointed by the court to conduct the defence of the assassin, Czolgosz, writes us that the alleged interview, a report of which was published in some of the daily newspapers, in which he was represented as stating his belief in the prisoner's insanity, was erroneous. We referred, in a recent editorial, to this alleged statement, and are glad to be able to chronicle the fact that such statement did not convey the counsel's opinion.

Current Comment.

THE PRESIDENT'S "ALIEN" NURSE.

In an editorial reference to the lamented death of President McKinley, *The Detroit Medical Journal*, in criticising the management of the case, mentions that "not only was Mrs. McKinley very carefully excluded from the sick room, but her spouse was left to the 'rule of thumb' care of an alien 'trained' nurse." Of the many criticisms of the case which we have noticed, this appears to us to be the most unhappy, unjust and uncalled for. In the profession of medicine, so cosmopolitan, so wide in its sympathies, so little influenced by the jealousies, narrowness and bigotry that divide people politically or religiously, it is fortunately rare that such an example of petty prejudice and intolerance appears as is displayed by the writer in question. It is not necessary, nor do we pretend to offer any defence for either the Canadian nurse who attended the President nor for the doctors who recommended her services. They, no doubt, had no other object to serve than their patient's welfare, and they were in the best position to judge of the fitness of the nurse in whose charge they left him.

That the Canadian Training Schools maintain as high an

educational standard and graduate nurses who are as thoroughly qualified for their professional duties, as any country in the world, is a fact that should be well known among our American friends, since a considerable proportion of the highest appointments in their best hospitals are held by Canadian graduates. During the President's illness it was no alien sympathy and interest which Canadians felt, and we doubt if his death was more deeply deplored or caused more sincere sorrow in the great republic itself than throughout the Dominion of Canada. The general sympathy displayed seemed to draw closer the two great branches of the English speaking people on this continent and its effect will not be lessened by any such exhibitions as we have referred to. It may possibly interest the writer of the editorial to learn that Miss Maud Mohan, of Brockville, the nurse in question, was alien only in birth, not in training, as she was trained in the Buffalo General Hospital, graduating from that institution in 1898, after which time she continued her professional services under Dr. Roswell Park.—*Canada Lancet*.

THE INTERNATIONAL CONGRESS OF NURSES.

The Nurses' Congress at Buffalo, U. S. A., was distinctly a success; it was well organized, and included some of the most distinguished women from the old and the new country. The subjects set forth for discussion dealt with hospital administration, the training of nurses, and their future spheres of work, remuneration and control, services under the State, and the duties of nurses as citizens or municipal officers. The discussions showed that the American women are much more apt in the public meeting than their English sisters, and also gave evidence that they are confronted with similar difficulties in organization. The American nurses are organized in a federation of two groups, "the Associated Alumnae," and the Society of Superintendents of Training Schools, and they work as one body in all matters of general interest to the profession. Three resolutions were passed as representing the results of the discussions, (a) in favor of higher education for nurses, (b) in favor of State registration and legislation, (c) condemnatory of the practice of sending out as private nurses pupils still in training at their schools. The Congress met with much sympathy and support from the public generally, and judging from the reception given to the nurses at the general meeting they are looked on as valuable workers in the interest of the community.—*The British Medical Journal*.

THE PSYCHOLOGY OF CROWDS.

M. Tarde, not long since, published a suggestive and important volume on the "Psychology of Crowds." He has now issued a new volume (not yet translated from the French, it is believed), under the title "L'Opinion et la Foule," says the New York Sun. The public is something different from the crowd. In a theatre or in the street the public and the crowd are the same thing. But printing and other modern devices have created a public which has an opinion independently of propinquity. Opinion is action at a distance.

The book in question studies the public, how it is born and developed, what its relations are with those who direct its opinions, its relation to the newspaper press, to crowds, to church and to state, its manners of action, its powers for good and evil. All these matters are fit subject for a strictly scientific treatment, which, in fact, they receive. The first printed book with a great public was the Bible; the Reformation was the result. It was, however, a long time before books were widely read. In the seventeenth century there was only a literary public, in the eighteenth a philosophic public arose.

Journalism came in with the Revolution. Public opinion in older times was formed only by conversation; with the advent of the press a new factor was introduced. The journal acts on the individual and the public reacts on the journal. In the last analysis, a public has the press it deserves. Points like the foregoing are treated in this book in an acute, original and suggestive fashion.

Philadelphia Press.

INSURING AGAINST SMALLPOX.

It's an ill wind that blows nobody any good, and the various insurances are reaping a tangible benefit from the smallpox epidemic. Several companies issue policies covering sickness not only from

smallpox, but from many other infectious diseases, enabling the insurer to draw a sum weekly during disablement, and in one case a company shows its firm faith in vaccination by offering to vaccinate its policy holders free of charge. *The Sunday Record.*

ALIEN—AN EXPLANATION.

Some of our Canadian friends are inclined to take umbrage at the employment of the word *alien* as it appeared in the September issue of this journal, and in connection with the nurse in attendance upon the late President. They seem to forget there may be another definition of *alien* aside from "a foreigner" or "citizen of a foreign country." It also signifies:

Pertaining to another; Not native; Estranged; Different in nature and tendency; Not a denizen or native.—*Worcesters' Unabridged Dictionary.*

Unsuitable; Strange; Hostile; Belonging to another person, place or thing.—*Encyclopædic Dictionary.*

One not having the rights of citizenship in his or her place of residence.—*Century Dictionary.*

The latter was the sense in which the term was used, the nurse being *alien* to Buffalo—as was necessarily the case when she was imported from Washington, D. C.

Detroit Medical Journal.

Reviews.

Handbook of Diseases of the Nose and Pharynx. By James B. Ball, M. D., (Lond.), Physician to the Department for Diseases of the Throat, Nose and Ear, West London Hospital; Lecturer on Diseases of the Throat, Nose and Ear, West London Post Graduate College; Formerly Physician to the West London Hospital. Fourth Edition. New York. William Wood & Company, 1901.

This volume, although not a big book, is just twice as large as that of the first edition, published in 1890. The increase is due chiefly to the addition of an article upon the pharynx and its diseases. If the author had included the larynx also and in the chapter upon General Diagnosis had illustrated and described instruments such as are more generally in use in this country, we should not hesitate to recommend it as one of the best of the text-books extant.

The chapters upon anatomy and physiology are especially good. The reputation that the book earned long ago depended largely upon this feature. The teaching in regard to pathology, diagnosis and treatment is conservative and yet entirely up to date. The author has no fads to exploit; he is careful to explain the technique of operations and gives full warning of dangers to be avoided. He does not dwell especially upon the histology of pathological conditions, for he has not wanted to make a big book, but where subjects, such as adenoid vegetations, reflex neuroses, hay fever, deformities of the septum, etc., subjects of great importance to the average physician, are treated, nothing is omitted that can give a clear understanding of the subject.

We are surprised to find that 10% to 20% solutions of cocaine are recommended for use in the nose. The author states that he has never seen any ill effects follow their use when applied on a swab, and ascribes all evil results to the use of cocaine in spray form. In the treatment of fetid atrophic rhinitis he favors the Gottstein method of tamponing the nostril with cotton wool soaked in iodo-glycerine, leaving some space in the inferior meatus for breathing. The specialist will find it a book well worth looking over. [W. G. B. H.]

Electricity in Medicine and Surgery. By William Harvey King, M. D., of New York; with a Section on Electro-Physiology, by W. Y. Cowl, M. D., of Berlin, Germany, and a Section on the Hottini Operation, by Alfred Freudenberg, M. D., of Berlin, Germany. Price \$3.50 net. Boericke & Runyon Company, New York, Publishers.

This work goes over well beaten ground of the employment of electricity in medicine and surgery. The Röntgen

rays receive special consideration in one chapter. Dr. W. Y. Cowl has contributed a section upon electro-physiology, while Alfred Freudenberg lends strength to the work by a chapter devoted to the Hottini operation. In our reading of the work, we were impressed with the many errors of typography, indicating great carelessness of proof reading, which seems almost inexcusable. [T. L. C.]

Thornton's Dose-Book and Prescription Writing.—Dose-Book and Manual of Prescription-Writing; with a List of the Official Drugs and Preparations, and the more important Newer Remedies. By E. Q. Thornton, M. D., Demonstrator of Therapeutics, Jefferson Medical College, Philadelphia. Second Edition, Revised and Enlarged. Octavo, 362 pages, illustrated. Philadelphia and London: W. B. Saunders & Company, 1901. Bound in flexible leather, \$2.00 net.

This is the second edition, thoroughly revised and enlarged, of Dr. E. Q. Thornton's excellent manual of prescription writing. The work is written for the student of medicine, and every feature has received the careful consideration of the author. We have not observed any inaccurate statements glossed over, and that part devoted to the explanation of the metric system is expressed with rare clearness. Prescription writing is a field in which the average graduate is sadly deficient when he starts out in his hospital career, and the careful reading of a little book such as this, in which the subject is handled with commendable simplicity and yet briefly, would do much to make prescribing a simpler task. The chapter upon the incompatibilities is entirely satisfactory, and this section contains references to the newer curative sera, organic extracts, synthetic compounds and vegetable drugs. Typographically, the book is all that can be desired.

[T. L. C.]

The Diagnosis and Treatment of Diseases of the Rectum. By William Allingham, F. R. C. S., Eng., and Herbert W. Allingham, F. R. C. S., Eng. Seventh Edition. 8 vo. pp. 471, New York, William Wood & Co. 1901.

This well known work preserves in the latest edition its essentially practical character. It has been subjected to revision and alteration, with a view, as the preface states, to condensation, and in order to keep it in accord with the recent advances in rectal surgery. The topics considered are treated in a satisfactory manner, without any attempt to go deeply into pathological investigations. Indeed its title shows that such studies should not be expected within its covers. It is this fact, perhaps, that makes the reader almost feel that there is something lacking in the volume. Its tone is that of conservatism; but its teaching is good in the main, even if its authors' views are not those of all surgeons. [J. B. R.]

The Influenza Bacillus Not the Cause of "La Grippe":—In *La Presse Medicale* (1901, No. 35) Rosenthal publishes more of his researches and experiments to show that influenza is not due to the Pfeiffer bacillus. For it cannot be found in many typical cases of influenza; and it is found in cases where there can be no suspicion of influenza. Rosenthal found the influenza bacillus in four adult cases, out of eight studied. Of these, only one was typical influenza. The others were cirrhosis of the liver with erysipelas, when no epidemic of "grippe" existed; acute croupous pneumonia following pneumococcal otitis media; and prolonged bronchopneumonia, almost typical of tuberculosis, yet with no traces of tubercle bacilli. It was not found, on the other hand, in two cases typical of influenza, a bronchitis due to enterococci, and a pneumonia due to pneumococci. It was also absent in an alcoholic pneumonia, and another non-tuberculous bronchopneumonia. Rosenthal's mixed inoculation experiments show that the influenza bacillus is rarely found, because, being aerobic, it will only grow upon blood-containing media. When it is methodically sought, it is found, like the enterococcus, pneumococcus, and streptococcus, "an ordinary microbe of the pathogenic flora of the lung." He hopes by mixed inoculation to find a serum treatment for these bacteria.

[M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Professor Waldeyer Honored.—A dinner was given at the University Club Monday evening, October 28, by the Medical Faculty of the University of Pennsylvania, in honor of Dr. William H. G. Waldeyer, professor of anatomy and director of the Anatomical Institute in the University of Berlin, who recently received the degree of LL. D. at the Yale Bicentennial. Dr. Waldeyer, who is an authority upon the microscopic anatomy of the neuron, ovarian cysts, carcinoma, the sclera, conjunctiva, etc., is 65 years old.

An Outing Given the Philadelphia Hospital Physicians.—On Sunday, October 27th, the City of Philadelphia invited the chief visiting physicians of the Philadelphia Hospital upon a tour for the inspection of the islands, to which it is proposed in the future to remove several departments of the Philadelphia Hospital. The visitors were taken up the river on the tug, Samuel H. Ashbridge, and stops were made at Burlington Island and Petty's Island, both of which were inspected. The guests enjoyed the bountiful hospitality of the city and all returned feeling satisfied that they had spent a thoroughly profitable day. The hosts upon this occasion were Mayor Samuel H. Ashbridge, Director of Public Safety English, and Dr. John V. Shoemaker, President of the Board of Charities.

The South Branch of the County Medical Society.—On Friday evening, October 25, a Southern branch of the County Medical Society was organized at Broad and Federal streets. Dr. W. S. Higsbee was elected chairman, and Dr. C. J. Hoban, clerk, for the ensuing year. A large number of representative physicians from the lower section of the city attended the meeting.

Society Meetings.—The following societies will hold meetings next week in the College of Physicians, at 8.15 P. M. Monday evening, November 4, Academy of Surgery; Wednesday evening, November 6, College of Physicians, and Thursday evening, November 7, Obstetrical Society.

Smallpox in Norristown.—Four houses are quarantined in the city of Norristown, and one in Norriton township. In one family four persons have been stricken with the disease. The Board of Health has decided that a municipal hospital is necessary, and steps are being taken to secure the old Globe Park Hotel at Oakview for this purpose.

Smallpox in Philadelphia.—The number of smallpox cases reported this week has slightly decreased, when compared with those of last week. The number of deaths remains about the same. Two school houses have been closed for disinfection during the week. Since March, when this epidemic began, over 400 cases have been reported, with 58 deaths. Most people have been revaccinated, in spite of the remedies now in use to prevent variola. It is reported that a Sister of Charity daily gives away thousands of bottles of a mixture of digitalis and zinc phosphate, which, after twelve drachms have been taken, is supposed to confer immunity to smallpox.

The Chief of the Bureau of Health has been notified by the Union Traction Company, that all its cars are nightly disinfected by being washed with a carbolic acid solution.

Vital Statistics of Philadelphia for the week ending October 26, 1901:

Total mortality	358	Cases.	Deaths.
Inflammation of the brain 10, bronchi 4, heart 1, kidneys 18, larynx 1, liver 2, lungs 37, pericardium 1, peritoneum 6, stomach and bowels 18			98
Marasmus 11, inanition 15, debility 4			30
Tuberculosis of the lungs			47
Heart-disease of 28, dropsy of 2, fatty degeneration of 3, neuralgia of 2			35
Uremia 11, Bright's disease 8, diabetes 1			20
Carcinoma of the liver 2, breast 1,			

	Cases.	Death.
stomach 5, uterus 2, pancreas 1 ..		11
Convulsions		6
Diphtheria	65	7
Brain-disease of 1, softening of 1, tumor of 1		3
Typhoid fever	56	4
Old age		11
Smallpox	59	19
Abscess, pelvic 1, alcoholism 1, apoplexy 16, asthma 2, burns and scalds 5, casualties 6, chorea 1, cirrhosis of the liver 7, child birth 1, croup 2, croup membranous 5, cyanosis 2, diarrhea 1, drowned 1, gangrene, leg 1, hemorrhage from stomach 2, hemorrhage from uterus 1, leukemia 1, obstruction of the bowels 1, paralysis 2, rheumatism 1, sclerosis, liver 1, shock, surgical 2, septicemia 2, sarcoma, stomach 1, stricture 1, suicide 2, teething 1, tetanus 1, tumor, uterus 1, unknown coroner case 1, whooping cough 2		76

NEW YORK AND NEW JERSEY.

To Test Koch's Theory.—Dr. George D. Barney, a specialist on tuberculosis, and Dr. Walter Lincoln Bell, veterinarian, of Brooklyn, N. Y., have secured a cow which they inoculated with human tubercular bacilli. By this experiment they expect to show conclusively the truth or falsity of Dr. Koch's proposition.

Dinner to Dr. Waldeyer.—On Saturday evening, October 26, a banquet was given at Delmonico's, by the Deutsche Medizinische Gesellschaft of New York, in honor of Professor Waldeyer, of Berlin. Among the speakers were Drs. W. H. Welch of Baltimore, A. Jacoby and Carl Beck of New York.

Dr. Charles Henry Brown, who died on October 15, 1901, in New York City, aged 45 years, was for years Managing Editor of the *Journal of Nervous and Mental Diseases*.

The New Hackensack Hospital.—The new building of the Hackensack Hospital, N. J., was opened to the public Saturday, October 26. The building accommodates 60 patients and has a fine operating room, the gift of the late Dr. E. E. Poor. The cost of erection was \$30,000.

New York State Medical Association.—At the annual meeting of the New York State Medical Association held in New York, October 21, the following officers were elected: President, A. A. Hubbell, of Buffalo; vice president, William H. Biggan, of Brooklyn; secretary, Guy Lombard; treasurer, E. H. Squibb.

A Remarkable Baby.—William Munion, of Pennsgrove, N. J., claims to have the prize baby in South Jersey. The child was ten months old on the 10th of October, weighs 41 pounds, has ten teeth, having been born with two teeth, and can walk anywhere about the house.

Smallpox in Camden, N. J.—The new Municipal Hospital is fast nearing completion, in spite of the protest of the residents of Woodlynne borough, adjoining the New Camden Cemetery property, upon which the hospital is being erected. Free vaccination is being given at the City Dispensary. No new cases have developed in the last few days.

NEW ENGLAND.

Yale Bicentennial Celebration.—Among those upon whom the degree of LL. D. was conferred by Yale at its Bicentennial, October 23, 1901, were Drs. William Osler, professor of medicine at Johns Hopkins; David White Finlay, professor of medicine at Aberdeen; Wilhelm H. G. Waldeyer, professor of anatomy and director of the Anatomical Institute at Berlin, and John S. Billings, of New York.

Smallpox in Newport, R. I.—Eight cases of smallpox have already been reported in Newport, all but one of them being traced to the first case, a Captain Evans, of the Salvation Army, who became ill two weeks ago. As the pest-house is overcrowded, the authorities have put immune carpenters at work upon an addition. The cases are all mild in character.

East Boston Ambulance Station.—For ten or twelve

years the residents of East Boston have been trying to secure a hospital or an ambulance station. It is expected at last that an order recently proposed, for an appropriation of \$18,000 for an ambulance station, will pass the Boston Common Council. A little building will be built in a few months, should this pass, near the docks along Marginal street and the great iron works and lumber yards along Border street, where most of the accidents occur.

Smallpox in Cambridge, Mass.—A case of smallpox was discovered in Cambridge, October 24, in a man of 20, who came to Cambridge about ten days before, from St. John, N. H., where six cases have developed in two days. The Board of Health seized a vacant house on New street, off Concord avenue, and the patient has been taken there. Three families in the vicinity left the neighborhood for the present.

WESTERN STATES.

New Laboratory in St. Louis.—Dr. R. Meade Bolton, of Johns Hopkins University, has been elected director of the newly opened laboratory of the Marion-Sims-Beaumont Medical College.

SOUTHERN STATES.

Dr. Rixey's Report on the President's Case.—Dr. Presley M. Rixey has just published his report of the wounding, illness, and death of the late President McKinley. The report is remarkable for its exhibition, in the closest possible detail, of the exact state of the patient during his illness. It is in the shape of a ship's log, showing at intervals of a very few minutes, sometimes a single minute, rarely more than an hour, the patient's progress toward the end. But perhaps the most valuable datum contained, from a medical point of view, is the accurate registering of the medication of the case—not a single morsel of food, a dose of medicine, or a bath is omitted in this account. Included in the running story, at the proper intervals, are the bulletins which were given to the public as the case progressed. The report begins with an account of the first operation at the emergency hospital, September 6, the two wounds being described exactly as they have been treated in the preceding medical reports. On the eighth and last day of the President's life, September 13, Dr. Rixey's report opened with this entry at 12.20 A. M., "restless, and complains of headache." Whiskey and water was given, and a perspiration was induced, but at 1 A. M. is this entry "very restless and wants to get up; tired." The same medical treatment was continued, involving a plentiful use of oxygen, digitalis, strychnine and morphia and peptonoids. Still at 4.55 o'clock the patient's condition is reported as grave. The oxygen was continued. There was no response to stimulants. Atropine and morphia were injected; the patient was almost pulseless. The last entry was made at 9 P. M., and there was a gap of five hours between that and the end. It read, "heart sounds very feeble. Oxygen continued. Slight reflex movements, and at 2.15 A. M., September 14, 1901, the President died." The cause of death is thus stated: "Gangrene of both walls of stomach and pancreas, following gunshot wounds." Attached to the report are the results of the autopsies and the chemical and bacteriological examinations, which have already been published in the medical journals.

The Clinical Society of Washington, D. C.—At a meeting of the Clinical Society of Washington, D. C., held October 11th, the following officers were elected for the ensuing year: Dr. Walter A. Wells, president; Dr. Monte Griffith, vice president, and Dr. J. Carlisle De Vries, secretary and treasurer.

Diphtheria in Baltimore.—Since the opening of the public schools, a marked increase in diphtheria has been noted. During September 60 houses, in which there had been cases of the disease, were fumigated. So far this month, 102 houses have been fumigated by the Health Department. Since January 1, 701 houses have been fumigated. The statistics of the Health Department show that since January 1 the city has handled 802 dead bodies, 137 of which were buried by friends.

Maryland University Hospital, Baltimore.—Nitrous oxide gas is being tried as an anesthetic in the Maryland University Hospital. After beginning narcosis with nitrous oxide, the rest of the operation is performed under ether. Good results have been secured.

Johns Hopkins University.—A large bronze tablet has

been placed in the hall of the Biological Laboratory of Johns Hopkins University in memory of Prof. Henry Newell Martin, first professor of biology and physiology in that institution. A meeting in memory of the late Prof. Henry A. Rowland was held October 6th in the physiological laboratory. Dr. T. C. Mendenhall, formerly president of the Worcester Polytechnic Institute, delivered an address. Dr. Sidney Cone, of the surgical dispensary of Johns Hopkins Hospital, has been appointed lecturer on orthopedic surgery in the Baltimore Medical College.

St. Joseph's Hospital Annex, Baltimore.—The new annex of St. Joseph's Hospital, the erection of which cost \$30,000, will be opened to the public November 5th.

Northeastern Dispensary, Baltimore.—The Northeastern Dispensary, on Monument street, which was opened in 1853, is erecting another new building, to cost about \$5000. Its equipment will probably cost another thousand dollars. The Dispensary treats about 7000 patients a year, filling 30,000 prescriptions. There are three resident physicians and three consulting physicians. The latter will soon be increased to twelve in number, and a board of lady managers will be selected.

The State Medical Society of Virginia will hold its thirty-second annual meeting in Lynchburg, November 5 to 8, 1901. Dr. J. R. Gildersleeve, of Tazewell, is president of the society.

Smallpox on the Eastern Shore.—The smallpox situation in Dorchester and Carolina counties, Maryland, has recently become serious, thirty new cases having been reported last week.

Precocious Maternity.—Dr. Allen reports the pregnancy and parturition of a colored girl aged eleven years, eight months, in the *Maryland Medical Journal*. Menstruation began at ten years three months. Her child, of normal size, was born at term without complications. Both mother and child are now perfectly well.

Maryland Medical College.—Dr. W. McLean Yost has been appointed associate professor of materia medica and clinical diagnosis, and Dr. P. E. Craig, associate professor of pediatrics.

Scarlet Fever in Putnam County, Georgia.—So prevalent has scarlet fever become in Eatonton and Rome, Georgia, that the public schools of Putnam County have been ordered closed for a month.

MISCELLANY.

Obituary.—Dr. A. A. McCain, New York City, October 19—Dr. G. M. Bartlett, Maryville, Tenn., October 22, aged 81 years—Dr. Leonard Latter, Monument Beach, Mass., October 22, aged 60 years—Dr. John D. White, Whiton, Md., October 23—Dr. G. G. Roy, Atlanta, Ga., October 24—Dr. Charles E. Stoner, Des Moines, Iowa, October 25—Dr. Charles Henry Brown, New York City, October 15, aged 28 years—Dr. George W. Burke, New Castle, Ind., October 18, aged 59 years—Dr. Charles H. Peck, Washington, D. C., October 25, aged 60 years.

Havana Health Report.—The report of the vital statistics for Havana shows 339 deaths during the month of September, 1901. There were only two deaths from yellow fever, seven from typhoid fever and three from diphtheria. No smallpox or scarlet fever was reported. During the six months from April to October, there were but five deaths from yellow fever. This condition has not been approximated at any time during the past 150 years. Since the first of March, 100 men have been engaged daily killing mosquitoes. The deaths from malaria have also decreased, being but eleven during the month of September. For September 1901 the death rate in Havana was 15.64 per thousand, while that of London was 16.57 per thousand. The most marked decrease among the infectious diseases was noted in yellow fever, malaria and tuberculosis. This was probably due to the improvement in interior hygiene and general sanitation. The streets of Havana are now kept in excellent condition. The sanitary officers believe that with their present disinfection methods they will be

able to stamp out any infection from yellow fever that may be introduced into the city.

The Expenses of President McKinley's Illness.—In the case of President Garfield, who lingered 80 days, a board of audit finally agreed to compensate the surgeons and physicians in the following proportions: Dr. Bliss, \$6500; Drs. Agnew and Hamilton, \$5000 each; Drs. Keyburn and Boynton, \$4000 each; and Dr. Susan B. Edson, \$3000. The board also allowed different parties \$5929 for services and supplies, including \$1500 to the Central Railroad of New Jersey, and \$1162 to C. Jones, of Elberon. Extra compensation was allowed certain Government employes, and the total expenditure was \$57,000. It is estimated that an appropriation of more than \$100,000 will soon be asked from Congress to pay the physicians and surgeons of the late President. Dr. McBurney's bill is expected to be at least \$25,000, and the other physicians will file claims in proportion.

Glycosuria from Cigars.—The occurrence of glycosuria has been noted following the excessive smoking of cigars, and is probably due to the carbon monoxide resulting from imperfect combustion. This may explain the glycosuria found among the beer drinking students of Jena. Only those who smoke cigars, not those smoking pipes or cigarettes, show glycosuria. Now that the smoking of cigars has become almost universal, this cause of temporary glycosuria should not be overlooked.

The Total Consumption of Sugar in the United States last year was 2,219,847 tons, and based on the average increase of 6.34 per cent during the past 19 years, the consumption this year should be 2,360,585. Of this quantity 1,000,000 tons in round figures will come from American sources, Louisiana being able to produce 350,000 tons. United States beet sugar factories 150,000, Hawaii 350,000 and Porto Rico 150,000, all being free of duty, leaving 1,360,585 tons to come from other sources on which duty is paid. The average duty assessed is \$36 per ton, or a total of \$48,981,060. The price of all the sugar consumed, however, being enhanced to the extent of the duty of \$36 per ton, or a total of \$84,981,060, it is evident that \$36,000,000 additional is paid by the people in order to provide the Government with 49 millions for revenue.—*Weekly Statistical Sugar Trade Journal*.

Leprosy in Crete.—Leprosy has existed in Crete from time immemorial. In spite of all the measures taken during the past centuries for its repression, the disease persists. The people who have always lived among the mountains have remained exempt. There are no rivers on the island, but the supply of fruit is ample, and there is excellent pasturage. Yet a large part of the population live chiefly on olives and bread dipped in oil. Snails, mussels, fish, and wine are also used as food. Out of the 200,000 inhabitants, there are almost 900 lepers, from Brunelli's report. Isolation was attempted years ago, but the disease persisted.—*Polielinic*.

Statistics show that in three hundred years the average length of human life has been doubled. In the sixteenth century it was between eighteen and twenty years; at the close of the eighteenth century it was a little over thirty years, and to-day it is over forty years.

Disease Transmitted by Ants.—An English doctor residing in Cyprus has encountered remarkable cases of disease being transmitted in the sting of the solitary ant. In one instance a woman was stung in her sleep by one of these insects, and the wound showed active signs of anthrax infection. It was then found that in the field adjoining her cottage there was a dead sheep, which had lain there for a week since it succumbed to that disease. Here, then, is yet another insect to be added to the growing list of those that, while not dangerous in themselves, are capable of great mischief owing to their transmission of malignant bacilli.—*Medical Press and Circular*.

The Stupidity of Eldest Sons.—The Japanese saying, *Soryo no jinroku* (a foolish eldest son), is certainly very old, but that it embeds a national belief there is little doubt. There are three causes for the intellectual inferiority of eldest sons among the better classes, they are the offspring of early marriages, begotten before the powers of their parents are fully matured; they are regarded from the first as the future inheritors of property and hence no pains are taken to teach them how to get a living for themselves; the first-born child is apt to be spoiled by its

parents. In reference to early marriages in Japan the following statistics are given bearing on the time of contracting marriage in various countries:

Countries.	Men.	Women.
Japan	22 yrs., 10 mos.	19 yrs., 4 mos.
Russia	25 " 2 "	21 " 5 "
England	28 " 2 "	25 " 5 "
America	30 " 9 "	28 " "
Switzerland	31 " 1 "	28 " "

Female education is progressing and early marriages are being discouraged, so that it is likely that the old saying given above will lose all its significance.—*Japan Daily Mail*.

The Vitality of Women.—Contrary to general opinion, women possess greater vitality than men. According to the statistics gathered by Dr. Brandreth Symonds, a study of the comparative mortality of the sexes at different ages demonstrates that in the first year of life the mortality of the female is much below that of the male, being 9.25% against 11.24%, and at the end of the first year 3.18% against 3.51%. This difference continues up to the fourth year. From five to twelve years of age, the female mortality is greater than that of the male, being .356% for males and .428% for females. At the age of 46, the male mortality equals that of the female, the latter having up to this time kept slightly in excess. During the years from 46 to 56, the period of the menopause, the male mortality gains rapidly, being .632% against .347% in the female per annum. Hence the period of the menopause is really a more serious age for men than for women. After fifty-six the female mortality increases, but is always slightly below that of the male. Women have not only a less mortality and a greater longevity than men, but there is also a plurality of female births.

GREAT BRITAIN.

King Edward's Illness.—*Reynold's Weekly Newspaper* of October 27th asserts that King Edward is suffering from cancer of the throat. It states that three operations have been performed for the removal of papillomata of the vocal cords since his accession to the throne. First the left vocal cord was affected, but last week a papilloma was removed from the right vocal cord. This operation was performed hastily, as there was great dyspnea. But it was regarded as only a temporary relief, the injured epithelium now having become cancerous, and serious developments are expected.

How Diphtheria is Spread.—In London it is the custom for children to see the body of a playmate who has died of diphtheria, in fact, these visits to infected houses seem to be the active causes of an outbreak of diphtheria. Sometimes a prayer meeting is held in the house, but this custom is being gradually abandoned. Dr. Thomas, the Merthyr Medical Officer of Health, mentions the fact that the children of neighbors have actually been allowed to kiss the body. He believes, and most medical men will agree with him, that it is unwise to kiss anyone suffering with, or lately recovered from, a sore throat of any kind.

Surgeon-General William Arthur Thomson, M. B., K. H. P., physician to the King, died October 6th at Camberley, Surrey, aged 71 years. He was graduated from Aberdeen University, and entered the army in 1851. He attained the rank of Surgeon-Major-General (afterwards Surgeon-General) in 1886, and retired in 1892. He was for a period Surgeon-General in India.

Dr. Edward H. Dickinson, F. R. C. P., died in Liverpool, October 10, 1901, aged 59 years. He was formerly lecturer upon comparative anatomy and zoology at University College, Liverpool.

CONTINENTAL EUROPE.

German Society for Orthopedic Surgery.—At the seventy-third meeting of German naturalists and physicians, recently held in Hamburg, a German Society for Orthopedic Surgery was formed. A committee of organization was appointed, consisting of Drs. Mikulicz of Breslau, Wolff of Berlin, Höftmann of Königsberg, Hoffa of Würzburg, Lorenz of Vienna, Joachimsthal of Berlin and Schanz of Dresden.

The Anniversary of Pasteur's Death.—On September 29, the sixth anniversary of the death of Louis Pasteur, a monument of Pasteur by the French sculptor, H. Dailhon, was unveiled at Arbois, where the savant was born. In Paris, at his tomb in the Pasteur Institute, services were held under the direction of Drs. Roux and Metchnikoff.

Obituary.—The death is announced of Dr. König, the French physician, who devoted so much time to physics, whose discoveries in acoustics, light, heat, and phonation brought him an enviable reputation, at his home in Paris. He was 69 years old.

Obituary.—Dr. Faure Miller, a well-known physician and member of the Anglo American Medical Society, died in Paris, October 28, aged 60 years.

Appointments.—Nantes: Dr. Malherbe, professor of anatomy, has been made director of the Nantes Medical School. Bremen: Dr. Herman Tjaden has been elected director of the State Bacteriological Laboratory, replacing the late Dr. Kurth. Vienna: Dr. K. A. Herzfeld has been appointed professor of gynecology. Tomsk: Dr. Smirnow has been appointed professor of histology and embryology.

The Virchow Celebration.—On Saturday, October 12, the day before the eightieth birthday of Rudolf Virchow, the first ceremonies in his honor were held in the Pathological Institute, Berlin. Besides the Berlin professors and many distinguished German statesmen, deputations of medical men from universities of the entire world were present. Welchelbaum, Toldt, and Chrobak, of Vienna; Chiari of Prague, and Escherich of Graz, represented Austria; Lister, Muir, and Pye-Smith, England; Baccelli and Maragliano, Italy; Lannelongue and Cornil, France; Ernst, Switzerland; Stokvis, Holland; Salomonson, Denmark; Hansen, Norway; Sundberg, Sweden; Schervinsky, Russia; Karamitzas, Greece; and Jacoby, the United States. When Virchow entered, he received an ovation. He spoke for nearly two hours, mainly upon the development of pathology. Surgeon-General Schaper then congratulated him, referring to the "gratitude of humanity for the blessings bestowed on the world at large by him whose motto had always been 'Let the safety of the people be the supreme law.'" In the evening a banquet was held in the lobby of the Lower House of the Prussian Parliament, which was prolonged into Sunday morning. The sum of \$12,500, subscribed by the medical men of Germany to increase the endowment fund of the Virchow Institute, was presented to Professor Virchow. Emperor William conferred upon Dr. Virchow the great gold medal for science, possessed by no living physician, and by only three members of the philosophical faculty of Berlin, one of whom is Mommsen, the historian. The King of Italy sent Virchow a gold medal bearing a portrait of himself. The German University of Prague conferred the honorary degree of M. D. upon Virchow, while the Berlin Ophthalmological Society elected him an honorary member. Addresses were presented from many American Medical Societies. Speeches were made in all languages, Baccelli speaking in classic Latin. Welchelbaum described the development of pathological anatomy, public health, and anthropology in Austria, commenting upon the influence of Virchow. Cornil, Pye-Smith, Stokvis, Schervinsky, Sundberg, Salomonson, Karamitzas, Jacoby, and others referred to the effects of Virchow's teaching in their respective countries. The students celebrated in their own way, with a "kommers" and a torchlight procession. The *Deutsche medicinische Wochenschrift* of October 10 appeared as a "Festnummer" in Virchow's honor; a "Festschrift" has been published containing a number of Virchow's best writings; and the *Wiener klinische Wochenschrift* and *Berliner klinische Wochenschrift* also published a Virchow number. It is further rumored that the Czar of Russia will confer the Order of the White Eagle upon Professor Virchow. Later an exhibition of the addresses, memorials, medals, pictures, statuettes, etc., presented to Dr. Virchow, was opened in the Kunstgewerbe Museum, Berlin.

Glanders in St. Petersburg.—Glanders is prevalent in St. Petersburg and several of the surrounding villages. About 700 horses suffering from the disease were destroyed since 1900. Two cases of glanders are reported in human beings.

The European Age for Marriage.—In Germany a man, in order to marry, must be at least eighteen years of age. In Portugal a boy of fourteen and a girl of twelve are con-

sidered marriageable; and at the same ages they may marry in Greece. In France, as in Belgium, the man must not be under eighteen and the "woman" sixteen. In Spain the intended husband must have passed his fourteenth year and the "woman" her twelfth, and this is also the case in Switzerland and Austria, with the exception that an Austrian girl must not be younger than fourteen, the possible age of her husband.

A Sanitary Bureau in St. Petersburg.—A central sanito-epidemiological bureau is being established by the Sanitary Commission of that city. This bureau will be connected by telephone with the city health offices and will have charge of all the information concerning infectious diseases. A number of rooms in connection with this bureau will serve for the temporary detention of people whose homes are subjected to disinfection. The bureau will also be equipped with special disinfecting apparatus and laundries. Special ambulances for the transportation of the sick are being prepared.

Medical Inspection of Factories.—The Medical Department is framing a law compelling the owners of mills and factories to hold a medical inspection at least once a week. Where women are employed, specialists in gynecology are to be called in.

Poisoning with Paris Green.—The workmen of a sugar-beet plantation in the village of Bogatoo, government of Kieff, suffered from wholesale arsenical poisoning as a result of working on beets which had been sprayed with Paris green. The latter is generally used on fruit trees as an insecticide, and as a rule there is no danger of poisoning, as long as several months are allowed for the arsenic to be washed off the fruits before they are handled or consumed.

Physicians in Germany.—In Germany there is one physician to every 2,058 persons, but only one drug-store to every 10,363 persons.

Prof. Koch Honored.—Emperor William has conferred upon Surgeon General Koch, the noted physician, the rank of major general in the Reserves.

A Diabolic Monster.—In Aragona, Sicily, a young woman recently gave birth to her first infant, a tiny, seven months child, with an oddly developed head. Above each eye projected a straight horn, as long as the mouth, and behind the ears, which were very large, other horns were visible. They were of cartilaginous material. The child's body was curved, shaped like that of the molluscae. To the body four tentacles were attached, bearing embryonal hands. The spine was prolonged into a tail, resembling that of a rat. It died a few minutes after birth. The Italian papers state that the mother went daily, during her pregnancy, to church, where she used to stare at the portrait of a child exactly like the one which she afterward brought into the world.

Open-Air Sanatoria.—Open-air sanatoria, now becoming so generally popular in Europe, are said to owe their origin to Miss Florence Nightingale. This notable woman first cured M. Benet, of Mentone, by advising him to pass the better part of his time out of doors, to reject medicines, and to apply himself to a liberal diet. The first establishment devoted to the open-air cure was founded at Görbersdorf in 1859 by Herman Brehmer, though it was left to his disciple and pupil Dettweiler to perfect the theory in the course adopted in 1875 at the sanatorium of Falkenstein. There are now in the Valley of Davos about 3,000 patients and sixteen physicians. The open air treatment for tuberculosis is astonishingly successful in Germany. Out of 142 attested cases in Hanover 121 are pronounced cured; in Saxony out of 98 patients 60 are cured, while in Baden, where the treatment is given in the pine woods of the Black Forest, 205 cases have been cured out of 240 under observation.

French Vacation Colonies.—The public schools of the eleventh district of Paris purchased a large place in the country three years ago, where over a thousand of the poorest and most delicate children of that part of Paris are sent each summer. The long vacation in France rarely exceeds eight weeks. An effort is now being made to have the rest of the twenty-two districts of Paris follow this example.

2.—The nature of those articular lesions that run a chronic course has most important bearings upon their treatment. There is a group of cases commonly met with among female patients in early or middle life. In which the disease is characterized by the frequent implication of the small joints of the hands and feet, by the symmetrical distribution of the lesions, and by the conspicuous degree of accompanying secondary muscular atrophy. The large joints suffer as well as the small, and those of the spinal column and the temporo-maxillary articulations are implicated in a large proportion of the cases. In a second group of cases, the majority of the sufferers are also females. In this variety the articular lesions tend to be symmetrically distributed, and the small joints of the hands are usually attacked. The patients are usually more advanced in life. The terminal joints of the fingers

are specially liable to be attacked, and with peculiar frequency the carpometacarpal joints of the thumbs are among the earliest articulations to be involved. Muscular atrophy is less conspicuous. If it should be eventually established that the conditions described really constitute two distinct diseases, the term *rheumatoid arthritis* should be used to designate the former, and the term *osteoarthritis* to indicate the latter malady, in which the bony changes are so early and conspicuously manifested. No one will contend that the nodular disease of elderly people is rheumatic in its origin; but this origin must be seriously considered in the etiology of the fusiform cases. The articular changes in rheumatoid arthritis are so obviously progressive that one cannot regard the condition as one of simple damage to the joints left behind from a rheumatic attack. An alternative possibility is that the rheumatoid changes may develop upon the top of a rheumatic attack, owing to secondary infection. In the great majority of cases, although there may be short prodromal periods of pain and stiffness without obvious swelling, rheumatoid arthritis has its characteristic features from the start and is not preceded by any attack which can be, with good reason, regarded as rheumatic. Nor does one expect the visceral lesions of acute rheumatism, and especially those of the cardiac valves, to be developed in its course. If there is any relationship between osteo-arthritis and gout, it is with the nodular or osteophytic form; but no single pathological theory will suffice to cover all cases. In the treatment of these cases, any debilitating influence that is constantly present should be relieved; if any unhealthy condition of the mouth or gums is present, it also should be attended to; the diet should be as nutritious as the condition of the patient allows, and meat should by no means be restricted. Stimulants, in some cases, appear to be beneficial. In order to keep up the patient's strength, tonic drugs, such as cod-liver oil, iron, and arsenic should be used, always provided that the drugs do not upset the digestion. Massage and passive movements of the joints themselves do more harm than good. Osler approved of the division of the chronic lesions of the joints, suggested by Dr. Garrod, namely: (1) an infectious group, comprising the spindle form in adults and the variety in children with enlarged spleen and enlarged lymph glands; and (2) the dystrophic variety, in which there were osteophytes, etc. An attempt has been made lately to separate as distinct maladies varieties of arthritis deformans characterized by rigidity of the spine without involvement of the joints of the limbs; and that with ankylosis of the vertebræ plus arthritis of the hips and shoulders. They were only varieties of arthritis deformans with special localization in the spine and not separate diseases. Armstrong believes that in all cases of arthritis there is more or less interference with the nerve nutrition of the affected joint or joints. In many cases of the rheumatic or gouty forms of arthritis the trophic factor is present in a small degree only, and these cases are readily amenable to well directed treatment. When the trophic factor predominates, the cases prove much more refractory. Cave said that since we know so little of the infective agent we can do little to destroy it by direct and specific remedies. But in every case, and especially in the early stages, let us search for a possible source of infection. The cavities of the nose and ear and their accessory sinuses, the buccal cavity, the whole extent of the alimentary canal and its diverticula, the skin, the respiratory tract, and the genital and urinary organs, should be inquired into, and, if necessary, scrutinized. West referred to a patient who was the victim of chronic joint trouble called rheumatic. Although he searched carefully for a source of infection, he could only find a slight degree of cystitis. The cystitis was treated on general principles and as it improved, the symptoms became relieved and, with its cure, disappeared. [J. M. S.]

3.—Williams and Stocker report a case of *cerebrospinal rhinorrhea* in a female patient, aged 40 years. The disease followed an attack of influenza. Running from the right nostril has continued night and day, without intermission, ever since. No cause for the disease is discoverable. [J. M. S.]

4.—Luff contributes a paper on the composition and therapeutic uses of the Cheltenham waters. [J. M. S.]

5.—Alcoholic neuritis is a peripheral neuritis associated with paresthesia and numbness in the limbs, atrophic para-

lysis of the arms and legs, and, in severe cases, of the trunk muscles, with great pain on pressure of the muscular masses of the limbs; there is hardly ever any paralysis of the cranial nerves or of the bladder or rectum. In addition there is frequently a dilated left heart with cardiac muscle failure and marked edema of the trunk and legs, and often albuminuria. At the Manchester Royal Infirmary the neuritis cases almost invariably occurred in men who took either beer only or beer in combination with spirits; while pure spirit drinkers seldom showed neuritic symptoms, but suffered more from delirium, mania and gastric or hepatic disturbance. During May and June, 1900, a considerable number of cases was seen, presenting unusual skin eruptions. Many patients had the characteristic signs of erythromelalgia, with great pains in the soles of the feet and palms of the hands; paresthesie, with marked erythema and profuse sweating of these surfaces; suffused running eyes, vomiting and diarrhea; and, at the same time, there was a much greater number of cases of herpes zoster than usual. A few weeks later Reynolds found that there was a veritable epidemic of alcoholic paralysis, and that these patients were also suffering or had suffered from some of the initial symptoms just mentioned. The occurrence of herpes suggested the possibility that arsenic was present in the beer, for every one of these numerous patients was a beer drinker. On November 17, some beer commonly taken by these patients, on chemical examination, yielded numerous crystals of arsenous oxide in a reduction tube by Reinch's test. The author traced the source of the arsenic to certain brewing sugars that were manufactured by the action of sulphuric acid on starches and cane sugar. It was also found that the sulphuric acid was very highly contaminated with arsenic. He obtained arsenic from the urine of one of the beer-drinking patients, and since then he has found it not only in the scales coming from the hands and feet, in the nails, and in the hair, but also in many internal parts of the body, including the brain. He has, in fact, clearly shown that arsenic, instead of being rapidly eliminated from the body, will accumulate to a considerable extent. The cases of neuritis seen during the outbreak of arsenical beer poisoning were characterized by their severity and by the tediousness of recovery. Perhaps the most prominent symptom was extreme tenderness of the affected muscles. The innervation of the heart was most profoundly affected, a condition which often led to unexpected death. In Manns' opinion the outbreak was entirely due to arsenic; although he admitted that alcohol probably played the part of a subcausal agent. He failed to obtain any chemical evidence that the arsenic existed in the beer in organic combination. There seems to be a strong affinity between keratin tissues and arsenic. Neurokeratin, which enters into the composition of nerves, forming a sheath round the axis cylinder and the white substance of Schwann, besides giving off numerous transverse fibrils, is closely allied to keratin. Neurokeratin also exists in the substance of the brain, the white matter of which contains about 10 times as much as the gray matter. A number of brains from cases of arsenical beer poisoning were divided into 2 portions, one consisting chiefly of white matter and the other chiefly of gray matter. Equal weights of the 2 portions of each brain were taken and submitted to analysis, with the result that the white matter invariably yielded more arsenic than the gray. It is probable that the immediate action of the toxic agent is not limited to the parts of the nerve which are undergoing degeneration. It is more than likely that the trophic centers in the brain are primarily affected, and that the nutrition of the peripheral neurons is thus interfered with. The storing up of arsenic in the neurokeratin, in close juxtaposition with the nerve elements, will keep them under its influence during the period of elimination as well as of absorption. He is disposed to regard the action of arsenic on the cells as interfering with their power of taking up oxygen and storing it in their protoplasm. Osler said that the cases of alcoholic neuritis seen in America were accompanied by the vasomotor paralysis leading to cyanosis of the extremities, a vivid erythema, sometimes with pain, and a glossy state of the skin. Pigmentation, keratosis, bullous lesions, and herpes he had never seen, although he had for many years been well acquainted with the skin lesions of chronic arsenical poisoning. Caton said that some cases

of neuritis in beer drinkers were due to the presence of lead, the lead being derived from the lead pipe which connected the beer engine in public houses with the cask in the cellar. [J. M. S.]

6.—Cases of rheumatism in which actual inflammation of the endocardium has commenced, should be treated with absolute physiological rest for at least 6 weeks, salicylates, small blisters to the wall of the chest between the clavicle and the nipple, each about the size of a florin followed by a poultice and one of those drugs that are believed to absorb effusions, such as sodium iodide. During the past 16 years, Caton has treated in hospital 92 cases of acute endocarditis by this method. Out of 61 cases in which a murmur was present at the time of the patient's admission to the hospital, 41 left it with apparently sound hearts, while in 20 the signs of valvular disease persisted. In 31 cases, on the other hand, the bruit and other signs of valvulitis came on while the patient was in the hospital; of these 28 left it with an apparently sound heart and 3 with permanent valvular disease. Osler said that he had tried for several years to carry out Dr. Caton's plan of treatment, but he had not been able to determine whether it had a distinctly beneficial action. The difficulty was to get at the subsequent history of the patients, and he would like to know the cardiac condition in the 69 cases, 2 or 3 years subsequent to the treatment. A patient might leave the hospital without a murmur, and yet several years subsequently signs of valvular disease might be discovered. It is not the vegetations in themselves that are serious, but the disturbance of nutrition started by their presence, a disturbance leading to show stenosis of the valve, and to progressive insufficiency. [J. M. S.]

7.—McPhedran and Goldie report the case of a man, aged 24 years, who complained of general weakness, heaviness of the limbs, palpitation, dull headaches, and an inaptitude for work. On examination few or no objective signs were to be found. He passed urine that was turbid and of an extremely bluish color. The pigment was readily extracted from the urine by chloroform and was believed to be indigo blue. [J. M. S.]

8.—The methods generally used for bacteriological analysis of pus are, as a rule, very imperfect. Cultivating the pus of appendicitis and other fetid processes in artificial media totally deprived of oxygen, Rist found that the germs seen in coverglass preparations of the pus that failed to grow on ordinary agar grew very well. By this method he has investigated cases of mastoiditis and he has found that such lesions caused by streptococcus or pneumococcus are very rare. In the greater majority of cases, mastoiditis has been preceded by chronic fetid otorrhea, and is itself of a very fetid character. These cases are generally severe, and liable to be complicated by either fetid or gangrenous suppuration, especially by disseminated metastatic gangrene in the lungs. They are caused by anaërobic germs, which are capable of mortifying and destroying the tissues by a process of putrefaction, as may be proved by inoculation of pure cultures in animals. The author has been able to find the same anaërobic microorganisms in the disseminated gangrene of the lungs caused by otitic septicæmia. He has described several new species of anaërobic germs, some of which seem to play a very important part in human pathology. These germs are extremely virulent and kill animals when inoculated into the peritoneal cavity under the skin, in a short time, after having caused putrid, gangrenous, and often gaseous inflammations. Some are morphologically very like the ordinary pyogenic organisms, but they are quite different biologically. *Bacillus racemosus* and *bacillus fragilis* seem to be the most active agents in appendicitis and pulmonary gangrene and are to be found in putrid pleurisy and otitic infections. *Staphylococcus parvulus* and *micrococcus fetidus* are also met with. Often aerobic germs, such as streptococcus or bacillus coli communis are associated with the anaërobic microorganisms, but their number is always comparatively small. Whenever there is a fetid suppuration or an active gangrenous process, anaërobic germs are at the bottom of it. It would be premature to draw from these facts therapeutic conclusions. But still, one is entitled to suppose that such antiseptics as potassium permanganate or superoxidized hydrogen, which possess a considerable oxidizing power, are to be preferred whenever there exists a fetid or gangrenous process. [J. M. S.]

9.—Rivière believes that enteric fever, dysentery, appendicitis, children's diseases, and acute illnesses in general are speedily cured by judiciously given calomel, which disintoxicates the whole organism and assures intestinal antiseptics. He also believes that typhoid and dysenteric lesions are produced by insufficiency and disturbance of the biliary function. He gives systematically to all his fever patients calomel and sodium bicarbonate, aa 0.25 cg. (4 grains) put directly on the tongue at midnight, followed next morning by castor oil beaten up with hot water or 8 grams of magnesia (for an adult). The fever always subsides by the next evening, sometimes on the very morning of the aperient draught. When fever is present he orders at his first visit, a few hours before the calomel, a large dose of sodium salicylate, 2 grams, as an antipyretic; this has, as everybody knows, a special elective action on the liver. To prevent the return of fever he always employs quinine, which favors the biliary function, but which requires the action of purgatives to eliminate the bile.

[J. M. S.]

10.—Williams contributes a paper on the treatment of phthisis by means of electrical currents of high frequency and high potential. After a few applications the temperature also in a severe case may be to 103°, but in from 12 to 24 hours it will come down, as a rule, to below the patient's lowest point. Later on, a stage is reached where even prolonged exposure to the high frequency currents will produce no rise and the patient is to all intents and purposes well. Cough after a few days is relieved, and after a few weeks is greatly lessened; though a dry cough without expectoration may persist for many months. Sputum, in a month or two, becomes *nil*. The bacilli, after a week or so, greatly increase in numbers; then they gradually decrease, and have a tendency to form "clumps." Perspiration subsides after a few weeks treatment. Body weight, as a rule, steadily increases with the improved digestion. The pulse rate is increased 20 or 30 beats during the actual application of the currents, but in a few hours or less it regains its usual rate. Anemia disappears and menstruation becomes normal. Tuberculous laryngitis seems particularly amenable to this form of treatment. Breathing becomes longer and easier. Of 43 cases, 42 put on weight, and lost all symptoms except in a few where a slight cough remained and a few bacilli were found occasionally. Physical signs generally remained long after the patient was at his maximum weight. [J. M. S.]

11.—The two commonest forms of cardioarterial disease are those in which there is diffuse arteriosclerosis and an hypertrophied heart, and those in which the vessels are less involved than the heart. The object of the treatment in these cases is so to affect either the heart or the vessels, or both, that a normal balance of work to resistance may be restored. In a case in which the arterial condition is chiefly one of slight loss of resiliency, whilst the heart is hypertrophied and its muscle is beginning to fail, the main indication is undoubtedly to save the work of the heart as much as possible. The regular administration of small doses of nitroglycerine is beneficial; but massage and restricted movements are strongly contraindicated as is also the use of digitalis, strychnine, or other heart tonics. Attention to the bowels, as in all cases of cardioarterial disease, is of the first importance. In those cases in which the disease has commenced in the vessels, the hypertrophy of the heart having only come on in response to the increased resistance which it has permanently to overcome, the object of the treatment is to increase the compensatory hypertrophy of the heart to a limited extent and, at the same time, as far as possible, permanently to lessen the resistance it has to overcome. In such cases the occasional exhibition of strephanthus, with at the same time the regular use of potassium iodide in small doses, resisted movements, carbonic acid baths and regular exercise slowly taken up gentle gradients are indicated. If gout is present it must be treated also. [J. M. S.]

12.—A patient presents himself with a history of emaciation, cough, and muco-purulent expectoration; there is a rise of temperature and night sweats. On examination there is found dullness over a portion of the lung, prolonged expiration, bronchial breathing, crepitation and moist rales. Are we justified in concluding from these symptoms and physical signs that the patient is suffering from pulmonary tuberculosis? The presence of tubercle bacilli in

two sputum proves conclusively the existence of tuberculous disease; but the difficulty arises when the examination of the sputum of the patient with above symptoms presents no bacilli. Muthu gave notes of 5 illustrative cases. He concludes: (1) That lesions and symptoms usually associated with consumption do not necessarily mean tuberculous disease of the lung; (2) that in every case presenting ordinary symptoms of consumption it is highly important that the sputum should be carefully and periodically examined; this will prevent error and insure more or less correct diagnosis; (3) that the terms phthisis, consumption, pseudo-tuberculosis, etc., are misleading and are loosely applied to denote pulmonary disease; (4) that failure to find bacilli in the sputum of a case of so-called consumption does not always mean absence of tuberculous disease. [J. M. S.]

13.—Wilkins reports a case of a woman, aged 65 years, who was suffering from what appeared to be rheumatic pains affecting the muscles of the arms and shoulders. She was treated with sodium salicylate, but the treatment did not relieve the pains, which became worse, especially at night. After the administration of 2½ minims of a 1 in 12 solution of morphine, hypodermically, she was found breathing noisily and, for a time, could not be roused. For several days after this the patient went on without any return of rheumatism. On the third day, the left lung became affected with pneumonia, which ran an ordinary course. When the patient was thoroughly convalescent from the pneumonia, she was allowed to go down stairs, after which she became much worse. At this time, she had a marked systolic murmur at the apex, and it was feared that an embolus had lodged in one of the small arteries of the brain. With the progress of the case the cardiac symptoms altered considerably. The murmur, which was audible at the apex, remained for 2 months or so and then gradually disappeared, leaving a murmur audible at the base. This basic murmur has now disappeared. A diagnosis of rheumatic endocarditis was made. [J. M. S.]

14.—Ross recommends a meat albumin dietary in the treatment of tuberculosis. [J. M. S.]

15.—In treating chronic bronchitis in those past middle life the toxicity of the blood should be kept as low as possible. The air breathed should be pure and nasal breathing insisted on. The diet should be a bare sufficiency, and alcohol and malt indulged in sparingly, or not at all. Every ounce of superfluous fat should be got rid of. The general health should be maintained at the highest possible level. A vigorous circulation should be maintained. Every precaution should be taken against breathlessness. Breathing exercises should be resorted to in order to preserve the mobility of the thorax. [J. M. S.]

3.—Alfred Cooper in discussing the present treatment of inoperable cancer urges upon the surgeon the careful study of these cases and the wisdom of trying various remedies suggested for their relief. He concludes by say-

ing: First, that in cases of inoperable sarcoma, particularly the spindle-celled variety, Coley's fluid should be employed since a certain number of cases have undoubtedly been cured in this way. Second, that in cases of inoperable cancer of the breast in women beyond 40 years of age and in whom the menopause has not occurred oophorectomy should be performed and followed by a course of thyroid extract. Third, that in cases of inoperable rodent ulcer and in other forms of malignant ulceration the Röntgen rays should be given a trial. Fourth, that in cases where the foregoing treatments are declined or are inadvisable the internal administration of celandine should be tried. When the cases are beyond doubt hopeless, morphia should be pushed without hesitation. These forms of treatment of inoperable malignant disease should only be suggested to the patient and their dangers and discomforts thoroughly explained. [J. H. G.]

4.—Gann through some recent discoveries in Central America proves the pre-Columbian existence of syphilis in the New World. The author writes that irresistible proof of this is evident, as it has been shown that the individual who was buried in a mound situated in the northern district of the colony of British Honduras, near the village of San Andres, died from syphilis. A number of clay figures have been discovered which lend support to the view that they represent individuals who suffered from syphilis. He concludes his article with a recapitulation of the main facts in the chain of evidence which we quote in substance: "1. The clay figures, indicating that the persons whom they were meant to represent suffered from some disease of the penis, confined apparently to the glans, a supposition which the life-sized penis tends to confirm. It is of course conceivable that, as these figures were dressed as priests, they may have been performing some ritual act of self-mutilation, a common occurrence, as we know from contemporary writers, amongst the Maya priests, but these acts were, as far as it is known, confined to cutting and slashing the limbs and drawing twigs and small ropes interwoven with thorns through a recently made slit in the tongue, no author having mentioned mutilation of the penis. 2. The condition of the tibiae which may, of course, have been due to caries or other morbid changes unconnected with syphilis; but when we remember that both bones were affected, that the tibiae are favorite sites for syphilitic morbid changes, and that the owner had evidently been afflicted with some disease of the glans penis, from which he presumably died, the evidence in favor of syphilis is overwhelming. 3. The peculiar and unique method of burial. We know from the accounts handed down by Sahagun, Torquemada, and other Spanish historians that amongst the aboriginal tribes persons who died from syphilis were not cremated (as was customary), but had a special mode of burial accorded them, and here, the author thinks, we have it before us." [F. J. K.]

5.—Marmaduke Shield reports a case in which a man, 60 years of age, forced into his rectum a gallipot which measured $2\frac{1}{2}$ inches in diameter and $2\frac{3}{4}$ inches in height. The patient made frantic attempts to remove it, but only managed to remove some pieces which he had broken off. The foreign body was so large and its edges so dangerous that Shield decided it could only be removed with safety through an incision of the rectum. A free incision was made into the rectum from behind and the foreign body removed with a pair of obstetric forceps. The wound was closed but subsequently had to be opened because of septic infection. Reference is made to many interesting cases of a like nature which have been reported. [J. H. G.]

6.—A. E. Maylard reports a case of laparotomy in which multiple abscesses and extensive intestinal adhesions together with an enlarged Fallopian tube were present. The patient was operated upon for symptoms of acute intestinal obstruction. After emptying the various pockets of pus, extensive packing was employed. The patient's condition upon the table became very alarming and the exact

source of the infection could not be learned. The patient made good progress until the ninth day after the operation, when symptoms of acute intestinal obstruction again appeared. When the abdomen was opened, a localized abscess was found encircled by loops of matted intestine. The pelvic contents were so matted together that it was impossible to separate them. At the upper part of the involved area a tense fibrous band was found extending transversely across the gut, producing complete occlusion. Another portion of intestine was found completely twisted upon its mesentery. These lesions were corrected with the greatest difficulty and only after an enterotomy had been performed. The abdomen was again packed with gauze, and the patient returned to bed. A fecal fistula persisted after this operation for some time, but it ultimately closed and the patient made a satisfactory recovery.

[J. H. G.]

7.—Stuart-Low states that mucin possesses most valuable therapeutic properties in certain gastric and nasopharyngeal affections. He has given mucin a thorough trial in a number of selected cases during the past 12 months and finds that it is a most valuable agent, often affording relief when other treatments fail. He recommends a tabloid composed of five grains each of mucin and sodium bicarbonate. In the treatment of nasopharyngeal affection he combines menthol with the tabloid mucin compound—dissolves these in water and uses this mixture as a douche. He mentions that a leading indication for the administration of mucin is the presence of a clean, red, angry or dry tongue, frequently a fissured tongue indicating a deficiency of gastric protective coating. Mucin also acts as a laxative. Mucin has been used with marked success in the treatment of gastric ulcers. [F. J. K.]

9.—Hoole reports a complicated case of placenta previa occurring in a woman 38 years of age. Forceps were applied, after separation of the placenta from the uterine wall as far as the fingers would reach, but failed to accomplish delivery. A leg was then drawn down and after severe traction a dead fetus was delivered. The patient made an uninterrupted recovery. [W. A. N. D.]

MEDICAL RECORD.

October 26, 1901.

1. The Prevention of Yellow Fever. WALTER REED and JAMES CARROLL.
2. On the Mode of Transmission of the Infectious Agent in Yellow Fever and its Bearing upon Quarantine Regulations. A. H. DOTY.
3. Arteriosclerosis, etc. CHARLES E. NANMACK.
4. Cinchonism and its Effect upon Articulation and Vocalization. CARL SEILER.

1.—Walter Reed and James Carroll published a paper recently read by them, on the prevention of yellow fever. They give some attention to the study of the mortality of this affection, and the study of its etiology. They were able to establish in the most conclusive manner that the mosquito serves as the intermediate host for the parasite of yellow fever. The doctrine of the spread of this disease by fomites must be cast aside to the great simplification of the problem how to prevent yellow fever, which they believe may be reduced to measures which shall prevent the propagation of this disease by mosquitoes. Although the specific agent of yellow fever has not yet been discovered, this must remain largely a matter of scientific interest rather than practical importance in its prevention. That variety of mosquito, which has recently been designated by Theobald, as a *stegomyia fasciata*, was formerly known as the *culex fasciatus*, and has become known as a prominent factor in the spread of yellow fever. They give a careful description of this insect, its habitat, its breeding places, the manner of deposition of the eggs, the length of generation. As to this point, they state that the impregnated female, having obtained a meal of blood, proceeds to deposit her eggs, in captivity, after an interval varying in their experience from two to thirty days; as a rule, the eggs are laid within seven days; sometimes a second or third meal of blood is taken before any eggs

are laid. The eggs begin to hatch, as a rule, on the third day, the period extending to about a week. The larval stage requires seven to eight days, and the pupal stage about two days. They discuss the influence of temperature on propagation, biting, and the interval after contamination before the mosquito becomes dangerous. The first special measure of prevention should be to protect the sick individual against the bites of mosquitoes, and they state that this can best be accomplished by thorough screening and with immovable screens. As it is possible that mosquitoes, that have already bitten the sick individual, may have escaped into other apartments of the house, they recommend that these should be closed tightly and subjected either to sulphur or to formaldehyde disinfection, or to the fumes of pyrethrum. They regard sulphur as the best agent. They state that in a well closed room, one to one and a half hours of sulphur fumigation, in a proportion of one pound to 1,000 cubic feet of air space, will suffice to destroy all mosquitoes. They close this important paper with the discussion of the measures to prevent the importation of yellow fever into the United States.

[T. L. C.]

2.—A. H. Doty presents a paper on the mode of transmission of the infectious agent in yellow fever and its bearing upon quarantine regulations. He gives a history of many of the methods adopted, and concludes by stating that the treatment of incoming vessels from ports infected with yellow fever is a very important matter. If they are five or more days in transit, and all on board are found to be well after a careful inspection, the vessel, its passengers, and crew shall be released. If the vessel has been less than five days in transit, all on board who cannot present satisfactory evidence of immunity should be removed and held for observation until the completion of a period of five days from the time of departure from the infected port, and then released only after a careful inspection. When yellow fever is found on incoming vessels, the procedure should differ only so far as it concerns the removal of the patient to a properly constructed hospital or apartment for treatment. He believes that the disease is not contracted by personal contagion or through the medium of clothing, bedding, cargoes of vessels, etc., and states that we are justified in changing our quarantine regulations to conform to these views. [T. L. C.]

3.—Charles E. Nammack discusses arterio-sclerosis; its importance, definition, etiology and symptomatology. The paper is a résumé of the opinions held on these points by Pepper, Tyson, Osler, Whittaker, Allbutt and others.

[T. L. C.]

4.—Carl Seiler discusses cinchonism and its effects upon articulation and vocalization. He states that the ordinary tinnitus aurium due to middle ear disease never transgressed the limits of pitch from 297 vibrations to 704 vibrations as the highest point, and that these subjective noises, although variable in quality or timber of the sound, had no appreciable effect upon vocalization or articulation; but they would invariably and very materially affect the perception of sounds which had the same, or nearly the same, number of vibrations per second. The subjective noises of so-called cinchonism as produced by the systemic toxic effects of various drugs, he found to be invariably of a very high pitch, varying from 1,584 to 3,960, and often higher. He states the interesting fact that among a few cases of musically educated persons whom he had the opportunity to examine and who were familiar with aural analysis of sound, inquiry elicited the fact that the noise was composite in character, being made up of a variable number of individual sounds. These were sometimes harmoniously blended, thus forming a chord, the fundamental tone of which, however, was always constant in pitch, but varied in its pitch with the drug producing the cinchonismal noise, and found this to be lowest when quinine, highest when salicylate of sodium was the cause. He also found that a combination such as is produced by the hissing of escaping steam or the noise of rapidly revolving grindstones, etc., not only interferes with the pronunciation of those consonants by which they are usually accompanied in articulate speech, such as the "th," "s," "sh," "z," but also caused them to be the most easily obliterated and consequently most difficult to be appreciated and recognized by the ear. [T. L. C.]

MEDICAL NEWS.

5. The Physician in Relation to the Dispensing of Medicine. J. TRACY MELVIN.
6. Anchylostoma Duodenale in Texas.

M. CHARLOTTE SCHAEFER.

1.—C. A. Powers reports a case of giant sacrococcygeal tumor which pursued an atrophic course. He states that some of these malformations are very common, and the most frequent seen is the simple dimple or groove, the so-called fovea coccygea. Beyond this there is the true epidermoid fistula or pilo-nodal sinus, and a step further brings the true dermoid. Sacculization of the cord connected with vertebral fissures and spina bifida occulta may also be placed in this class. There is also a class of complex growths, complete or incomplete double formations, and parasitic mixed tumors (teratomata-embryoid tumors). These tumors present the greatest diversities of tissues. They are generally mixed, and in addition to the structure of dermoids, they may and often do present cysts lined with ciliated, flat or columnar epithelium, muscle fiber, nerve tissue, intestinal remnants, bone and cartilage. The case reported belonged to the latter class.

[T. M. T.]

3.—J. Darier defines biopsy as a sort of autopsy upon the living. It is the excision of an eruptive lesion, or a fragment of tumor, for the purpose of establishing the diagnostic histology of a malady. The instruments required are a von Graefe knife, anatomical forceps, histological scissors, either straight or curved, with blunt ends: these are sterilized. The operator's hands are washed; the field is disinfected. If the patient is timorous, anesthesia is obtained by means of an ethyl-chloride spray; a disadvantage of this method is that when the tissues are congealed, it becomes difficult to distinguish the element chosen for incision. To overcome this obstacle the part may be previously marked with ink; another method is to postpone the operation until the blanching of the skin disappears—anesthesia is not complete at this moment, but there remains a sort of stupefaction of sensibility. Subcutaneous injections of cocaine must be rejected absolutely in this operation, because of the local edema which they produce, and the interstitial hemorrhage provoked by the needle, and the alteration in the tissues which results from contact with an aqueous liquid. But in ulcerations and erosions of mucous membranes one may apply locally a cotton sponge soaked in solution of cocaine, 1 to 10. Practically local anesthesia may generally be dispensed with. It is well to remember that the best analgesic is an exceedingly sharp instrument. In making the incision the operator picks up the selected part with the thumb and forefinger of the left hand; this fold is transfixed at the desired depth by the Graefe knife, which is plunged beneath the portion destined for excision; the knife cuts a flap which includes the desired piece. The flap is picked up with forceps, is detached at the base by the scissors, and the section is immediately plunged in the fixing fluid. Hemorrhage is usually insignificant, but is somewhat more abundant where an anesthetic is employed. A good local hemostatic is a fine powder of juniper wood, sterilized by heat and impregnated with vapor of creosote. This is superior to antipyrin and more practical than gelatin, which must be softened by heat. Sutures may be resorted to after deep and wide excision of healthy tissue—a rare condition in biopsy. A simple dressing of iodoform gauze held with collodion suffices. There are two distinct classes of cases in which we can use biopsy. (1) Those in which the indication is absolute and pressing, including tumors and ulcers of doubtful character which tend to invade surrounding

tissues, such as tumors of the tongue, lips and face; (2) In the case of multiple tumors, annoying to the patient, but unquestionably benign, or of a persistent eruption of indeterminate character. [T. M. T.]

5.—J. T. Melvin concludes his article by saying he would only enter a plea for a thoughtful recognition of the changed conditions of to-day, and for a return to that accurate, well-trained clinical observation of the actual effects of every remedy administered by the physician in each case that he treats, to the end that the vast mass of therapeutic trash which now confuses and misleads practitioners may be wholly swept away, and that the physicians of the present and future may be so trained and educated as to give to this most important branch of our profession that same skilled attention, born of scientific laboratory methods, which they now give to differential bacteriological diagnosis or to blood examinations.

- 2.—Will be abstracted when finished.

4.—In cases of tuberculous peritonitis with ascites and encystment, if the kidneys are diseased or if the lungs are extensively involved, laparotomy is contraindicated. In the uncomplicated cases it would seem the part of wisdom to give medical treatment a thorough trial. If the patient does not quickly improve, then laparotomy should be resorted to, before the stage of encystment has progressed too far. The nodular form of tuberculous peritonitis is also regarded as a most favorable one for operation. [J. M. S.]

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

October 26, 1901.

1. Removal of Foreign Bodies from the Air-Passages.

DEFOREST WILLARD.

2. The Treatment of Empyema. JAMES H. DUNN.

3. The Treatment of Strabismus other than Operative.

EDWARD JACKSON.

4. The Strabismus Operation. C. F. CLARK.

RICHARD DEWEY.

8. Syphilis of the Nervous System, etc. F. W. LANGDON.

9. Preventable Diseases in the Army of the United States, etc. MAJOR W. O. OWEN.

1.—DeForest Willard concludes an article on the removal of foreign bodies from the air passages as follows: 1. Coughing should be encouraged; forcible inspiration restrained. 2. Inversion in the prone position as a domestic practice is advisable. 3. Laryngoscopy is helpful if the body is lodged at the vocal bands. It may be extracted by forceps or by laryngotomy. 4. If time permits the X-ray may be brought into serviceable use for diagnosis. 5. Careful diagnostic investigation is important to determine the actual presence of a foreign body, and its location. 6. Tracheotomy under local anesthesia should be the rule if the object is lodged at the bifurcation or in the bronchi. Tracheoscopy, suction and forceps' manipulation must be cautiously employed. Prolonged instrumentation adds greatly to the danger of pneumonia. 7. If extraction is not

secured through the tracheotomy wound, the chest wall should not be invaded, unless an artificial respiratory apparatus like the Fell-O'Dwyer is at hand and oxygen available. With the assistance of these appliances, however, the bronchus may be reached either anteriorly or posteriorly, since by their use, rythmical movements can be maintained. 8. Resultant abscess of the lung should be treated by incision and drainage. [F. T. S.]

2.—Dunn deplores the present unsatisfactory treatment of empyema; this is due to tardy diagnosis, inefficient drainage and slovenly after treatment. He usually resects 6 cm. of the 8th rib, just outside the angle of the scapula, thus insuring adequate drainage because of the low position of the opening, and allowing careful examination of the cavity because of its size. Whenever possible the fluid drawn off by the exploring needle should be examined bacteriologically before operation is decided upon. If a pure pneumococcus infection be found, or the fluid be a sterile serous exudate such as is found in tubercular empyemas, repeated aspirations may be tried before incision and drainage. In large and double effusions gradual evacuation by paracentesis is advisable several hours before rib resection. Light chloroform anesthesia should be employed or, if there be contraindications to this, the operation may be performed under Schleich solution; ether should never be used. Wiping the cavity with gauze is less objectionable and more efficacious than irrigation. The indications usually given for lavage, abundant discharge, fetor, and fever, do not demand irrigation but a free opening. For drainage gauze is preferred as the opening early contracts around a rubber tube. Attention to respiratory gymnastics is of great importance in the after treatment. The contraction of the cavity comes to a standstill in several months and this is due, not to the ribs, but to the thickened and rigid pleura, hence the operation of choice is the Schede. [F. T. S.]

3.—Edward Jackson presents an article on the treatment of strabismus, other than operative. He states that a large number of cases may be cured without operation. The non-operative treatment for strabismus includes: 1. The bringing about of normal innervation of the muscles concerned in ocular movements, by the removal and exclusion of abnormal requirements, and abnormal overflow impulses; 2. To place and keep the eye, so far as possible, upon the best plane of visual acuteness and an equality of required effort; 3. To eradicate abnormal methods of using the eyes, especially dependence of one eye to the practical exclusion of the other; 4. To develop normal binocular vision—the method of combining the visual sensations produced by the two eyes; and the habit of employing them both in all ordinary seeing. He takes up the questions of the use of the previously deviating eye, the use of cycloplegics, and exercise for the development of binocular vision; the reflecting stereoscope, the ordinary stereoscope, and the reading bar.

[F. J. K.]

4.—C. F. Clark describes the strabismus operation. The various operations resorted to for the correction of strabismus may be classified under the following heads: Tenotomy.—1. Partial division of the tendon (graduated tenotomy). 2. Complete division of the tendon. 3. Complete division of the tendon, with division of the lateral fibres of the capsule. Advancement.—1. Partial advancement of the tendon (graduated advancement). 2. Complete advancement of the tendon. 3. Complete advancement of the tendon with advancement of the capsule. 4. Resection of the tendon. 5. Resection of the tendon and capsule. After fully discussing the various measures of treatment, he concludes that in the correction of strabismus, advancement, or resection combined with a very little tenotomy, should, as a rule, be substituted for simple tenotomy. [F. J. K.]

5.—L. Breisacher presents a paper on artificially prepared foods, their nutritive value and dietetic application. He discusses the caloric value of food stuffs and their relation to body weight. The fundamental principles, by which it is necessary to be guided in both health and disease, empha-

size the fact that of the three chief nutrients—albumin, fat and carbohydrates, to which a fourth, gelatin, may be added—albumin is the substance which requires the foremost consideration in the selection of a diet. This is true, because it can not be replaced by any other known nutrient, whether it belongs to the nitrogenous or non-nitrogenous group of chemicals or food-stuffs. He discusses the question of artificially prepared or pre-digested foods, and states that, on the whole, artificially prepared starches given alone or mixed with especially prepared milk foods have given good results in his hands. When used with judgment and discretion they often render valuable service. When they are indiscriminately prescribed, they give correspondingly bad results. [F. J. K.]

6.—Patrick lays down the following postulates relating to **cerebral syphilis**: That 50% of all cases occur within the first three years after infection and after ten years it is rare; that in reaching a diagnosis the absence of a history of chancre should have no weight in women, and but little weight in men; that brain syphilis most frequently means arteritis, next meningitis and infiltration of the cranial nerves, while gumma is the least frequent; that paralysis from cerebral syphilis, excluding paralysis of the cranial nerves is more frequently caused, neither by gumma nor hemorrhage, but by thrombosis due to arteritis; that the condition is more amenable to treatment than cerebral thrombosis due to other forms of arteriosclerosis; and that syphilis does not involve systems. The condition lacks type in its manifestations and conforms to no rule. Headache is present in about 75% and frequently some part of the head is tender to percussion. Various forms of fits occur. Epilepsy or apoplexy between 20 and 40 should always awaken suspicion of specific disease. None of the cranial nerves is exempt from involvement, the muscles supplying the eye suffer most often, next the fifth, seventh and eighth nerves. Beyond the eighth they are infrequently affected. The addition of spinal cord symptoms, increase of deep reflexes, and incoordination contribute to the formation of a diagnosis. The peculiar stupor which has been likened to the drunken state, when combined with other signs, is almost pathognomonic. Fever is rare unless the pons or medulla is invaded. Vomiting occurs in many cases, especially when the posterior fossa is involved. Polydipsia, polyuria, and polyphagia are not unusual, the last being the least frequent. Insomnia, aside from the inability to sleep on account of pain, is not rare. [F. T. S.]

7.—Richard Dewey thinks that there is possibly nothing distinctive of **syphilitic psychoses**. The bizarre and irregular character, the tendency to remissions and to return to apparent sanity, etc., are seen in other forms of insanity. The fact that the anterior portions of the brain are more open to specific infection gives some significance to the frequency of dullness and stupor. [F. T. S.]

8.—F. W. Langdon presents a paper on **syphilis of the nervous system**—its general pathology, with remarks on treatment. The initial lesion of syphilis must be viewed, in the light of our present knowledge, as a wound plus infection, the infecting material being probably of bacterial origin. The conditions found in the nerves are described as, 1, obliteration of lymph spaces; 2, disappearance of axons; 3, a "glassy" degenerated appearance of the myelin. Syphilitic multiple neuritis has also been reported. The second evidence we have of the invasion of the nervous system by the disease or its products, is in the production of fever—"syphilitic fever"—often overlooked and sometimes misinterpreted. The third group of processes to be considered, and by far the most important, is the inflammatory group whose characteristic lesion we call a "gumma." Remedies of value in syphilis may act in three ways: (a), the most usual, by promoting necrosis in the embryonic cells of the exudate, thus permitting their removal in large part by the lymph channels; (b), by stimulating the excretory organs generally, thus favoring removal of "toxins" produced by the disease; (c), possibly by the promotion of leukocytosis

and other tissue changes, which set free an increase of the natural amount of antitoxin. The discovery of a means of producing artificially an antitoxin which shall arrest the disease in an early stage, must be conceded as a possibility.

[F. J. K.]

9.—Major W. C. Owen discusses the **preventable disease in the army of the United States**, its causes, effects and remedy. He believes that the day has come when all sanitary matters of the army should be placed under the control of the Army Medical Department. He discusses the various measures by the following out of which the mortality of the troops may be reduced. The question of transportation is taken up, and the articles of the Geneva Convention are quoted and discussed, as well as the question of the responsibility of commanding officers. He includes in this paper a copy of a bill presented on December 6, 1900, by Mr. Hay in the House of Representatives, defining the duties of the Medical Department of the Army of the United States. [F. J. K.]

AMERICAN MEDICINE.

October 26, 1901.

1. Transmission of Tuberculosis Through Meat and Milk. (Continued.) JOHN J. REPP.
2. Symptoms, Diagnosis and Treatment of Enlarged Prostate Gland. CHARLES J. WHALEN.
3. Report of a Case of *Filaria medinensis*, Guinea-Worm Disease. EDWARD FRANCIS.
4. Analgesia from the Spinal Subarachnoid Injection of Cocain. J. GARLAND SHERRILL.
5. The Use of Ethyl-Bromid as a Primary Anesthetic to Ether or Chloroform. EMERY MARVEL.
6. Chorea With Partial Paralysis Secondary to Rhinitis. C. FONTAINE-MAURY LEIDY.
7. The Lane Lectures on the Social Aspects of Dermatology VII. MALCOLM MORRIS.

1.—John J. Rapp contributes an article on the **transmission of tuberculosis through meat and milk**. He gives a résumé of the literature and the opinions held by many authorities on this subject. He treats the subject under two general subdivisions. (1) The transmission to animals, and (2) transmission to man. Under the transmission to animals he discusses infection by meat and by milk. He mentions the great lessening of tuberculosis in calves of tuberculous cows which have been separated at birth and fed on sterilized milk or the milk from sound cows, and refers to the numerous observations of veterinarians pointing to the transmission of tuberculosis from cows through their milk to calves and swine. He states that it is proven that tuberculosis may be transmitted through the milk and the food structures of tuberculous animals to the animals that consume these products or are inoculated with them, but that this does not decide the important question at issue, whether or not tuberculosis is transmissible from animal to man. Under the head of transmission to man, he discusses transmission by meat and by milk. He mentions the statistics collected by Thorne from physicians in Ohio, as especially valuable. He states that there is no evidence that tuberculosis is not to some extent transmitted from animal to man through ingestion of meat. The article is continued. [T. L. C.]

2.—Charles Whalen discusses the **symptoms, diagnosis, and treatment of enlarged prostate gland**. He gives a résumé of the subject and presents his conclusions that **prostatectomy** and **Bottini's galvano-cautery treatment** are the only ones to be considered at the present time. The indications that will decide upon which operation should be performed are: The age of the patient; the size of the prostate; the condition of the kidneys and bladder. He advises that spinal anesthesia be used in place of the usual anesthetics. [T. L. C.]

3.—Edward Francis reports a case of **filaria medinensis, guinea-worm disease**. It is a tropical affection, due to the *filaria medinensis*, an animal parasite inhabiting the human connective tissue, and belonging to the nematodes. The patient in whom this condition was present had been only 40 days from Guinea. The life history of the worm is given with cuts, and a photograph is presented of the patient's feet, showing four worms protruding. [T. L. C.]

4.—J. G. Sherrill discusses **analgesia from the spinal sub-**

arachnoid injection of cocain. He deals with the probable dangers from the injections into the spinal cord, including the shock of tapping the cord and injecting cocain; the danger to the cord and centers in the medulla; the action of cocain upon the heart; the immediate danger of infection through the puncture. He concludes that cocain is not likely to prove satisfactory in operations above the level of the diaphragm; that probably it will not be much used in abdominal cases which are not clear, and are likely to prove tedious or difficult; that its special field will be found in operations upon the lower extremities, including amputations and resections, and upon the perineum, bladder and rectum; also that it is useful in operations on old persons and those suffering from disease of the heart, lungs, or kidneys, from cirrhosis of the liver, and from abdominal dropsy; and that it can be successfully employed when a patient fears general anesthesia. He gives his experience with the method in 27 cases. [T. L. C.]

5.—Emery Marvel presents a paper on the use of ethylbromid as a primary anesthetic to ether or chloroform. He records 36 operations in which the method was successfully employed with no disadvantages, unless it be the odor of garlic of the patient's breath. [T. L. C.]

6.—C. F. M. Leidy reports a case of chorea with partial paralysis secondary to rhinitis. He attributes the condition to septic infection from the nasopharynx with improper oxygen of the blood due to the obstructed air passages. He has found no similar case reported. [T. L. C.]

UNIVERSITY OF PENNSYLVANIA BULLETIN.

July, 1901.

1. Memoir of William Pepper. JAMES TYSON.
2. A Report of the Nasal Septum as Found in the Skulls of Forty Mound-builders. GEORGE B. WOOD.
3. Report of the More Interesting Obstetric Operations and Cases in the University Maternity, from September to January, 1900. A. H. REMINGTON.
4. A Statistical Digest of Epithelioma of the Penis.

FRANCIS DENISON PATTERSON.

5. A Series of Twelve Articles on Medical Men Prominent in the Civil and Military Affairs of Revolutionary Times—V. FRANCIS R. PACKARD.

1.—Prof. James Tyson contributes a memoir of the late Dr. William Pepper, which is an admirable and just estimate of one whose attainments covered far more than the field of medicine in which he was so eminent. No mere abstract of this paper could give an adequate idea of Dr. Tyson's just tribute. [T. L. C.]

2.—George B. Wood presents a report of the nasal septum as found in the skulls of forty mound-builders. He has classified his findings into three groups: those in which the deviation was only four-tenths centimetre or less; and those in which the deviation exceeded four-tenths centimetre. In three cases the septum was apparently straight except for a spur or ridge; this equals $7\frac{1}{2}$ per cent. of the septums examined. The septums were found straight and in the median line in 13 cases, i. e., $32\frac{1}{2}$ per cent. In nine cases, or $22\frac{1}{2}$ per cent., the deviation was only four-tenths centimetre or under, and in 15 cases, or $37\frac{1}{2}$ per cent., the deviation exceeded that amount. Thus, it will be seen that a perfectly straight condition of the bony portion of the septum existed in only $32\frac{1}{2}$ per cent.; and this does not exclude any possible deviation of the cartilage which might have existed during life. Of course the lesser deviations and spurs, which probably would not cause any inconvenience to the person in which they were found, would raise this per cent. up to $62\frac{1}{2}$. These results correspond closely with those of Price-Brown, and tend to disprove the theory that the commixture of races is accountable for the great majority of those septal deformities which develop during the growth of the child. [T. L. C.]

3.—A. H. Remington reports the more interesting obstetric operations and cases in the University maternity from September to January, 1900, with notes of cases of abdominal section for ovarian cyst stimulating pregnancy; a case of abdominal section for an extra-uterine pregnancy, or pyosalpinx; a case of ruptured symphysis pubis; one of septic salpingitis after a missed abortion, and one of ventrosuspension during the puerperium for prolapsed uterus with the repair of cystocele and rectocele. Three cases are also detailed of complete tear through the sphincter.

There is given an account of a small sloughing submucous uterine fibroid at the fundus, causing sepsis after labor, a case of mitral disease and induced labor, and one of pregnancy complicated by a previous ventrosuspension of the uterus. [T. L. C.]

4.—Francis D. Patterson contributes an extremely exhaustive, searching, statistical digest of epithelioma of the penis in which 359 cases are collected. The etiology, symptoms, pathology and method of extension of the disease and complications are discussed, as well as the diagnosis, prognosis and treatment. In conclusion, Patterson states: 1. That epithelioma is by far the most frequent form of carcinoma of the penis, and that its frequency is about 2 per cent. of all cancers. 2. That phimosis is a strong predisposing factor by causing chronic irritation. 3. That, as a rule, epithelioma is more frequent after middle life, though, like every other rule, this has its exceptions. 4. That the syphilitic virus has absolutely nothing to do with epithelioma, the scar of the old specific lesion being nothing more than an area of decreased resistance or a cause of chronic irritation. 5. That traumatism is a predisposing factor by causing an area of decreased resistance. 6. That the question of the contagiousness of epithelioma is still to be decided. 7. That epithelioma more commonly begins in the glans or prepuce, and that origin in the urethra is very rare. 8. That visceral metastasis is very rare. 9. That the prognosis in the precancerous stage is favorable if radical treatment be at once instituted; later it is only guardedly so. 10. That the only safe treatment in any stage consists in the thorough eradication of the area of disease and of all lymphatic glands that are involved. [T. L. C.]

5.—Francis R. Packard continues his series of articles on medical men prominent in the civil and military affairs of revolutionary times. In this paper a brief sketch is given of Dr. Cadwallader Colden, a Royalist Governor of New York. [T. L. C.]

8. Note Upon a Case of Cardia Duplex in a Turkey.
ALLEN J. SMITH.

1.—Opie reports an interesting case of filarial infection. The patient, a man of 24, had been born in the Island of St. Thomas. A few days before admission to the hospital he had a severe chill and went to bed. There was high fever, leukocytosis, and a tumor in the right groin which was found to consist of a mass of dilated blood channels and spongy tissue, and there were symptoms of peritonitis. The abdomen was opened and pus and fibrin were found in the peritoneal cavity, but no cause was found for their presence. The patient died, and at the autopsy a huge lymphatic varix was found in the abdominal cavity surrounding the aorta and its branches, and extending along the spermatic cords. The vessels contained a dark thrombotic material. A portion was excised from the left epididymis and in it a mature filarial worm was discovered. Lanceolate diplocoeli were found in the fluid from the pleura and the peritoneal cavity. Among the interesting features of the disease is the fact, that the lower lymph vessels are usually filled with blood. He gives a careful discussion of the literature. [J. S.]

2.—White and Pepper report the results of their studies upon the blood of persons suffering from lead-poisoning or exposed to lead intoxication, in heat cases, and in animals subjected to experimental poisoning with lead. In 4 cases of chronic lead poisoning basophilic granules were

found in the blood of all. In 21 cases of lead workers without subjective symptoms, whose period of exposure varied from 4 days to 24 years, all showed more or less basophilic degeneration. In none of the cases exposed to heat were they able to discover any signs of this peculiar change in the erythrocyte. In animals slowly poisoned with acetate of lead basophilic degeneration appeared after the initial dose, and the cells were more frequent in the blood taken from the abdominal veins than in that from the periphery. The granules were not found in preparations of the bone marrow. They conclude that these basophilic granules are constant in lead poisoning; disappear during convalescence; that immunity to lead never occurs; that basophilic degeneration may be produced experimentally by poisoning with lead, and that it always represents a true degeneration of the erythrocyte. [J. S.]

3.—Johnson reports a case occurring in a child of 4, who had a severe inflammation in the throat. Subsequently there was a swollen mass in this region, the patient had a profuse hemorrhage from the left ear, and finally symptoms of pressure upon the trachea. Tracheotomy was performed, and the patient did well for a time. He then developed bronchitis, and had a severe hemorrhage from the mouth and nose causing death. A diagnosis was made of dissecting aneurysm of the internal carotid. [J. S.]

4.—Lo Conte reports the case of a mulatto woman 27 years of age, who had an enlargement of the left axillary region. Subsequently there was a tumor of the mamma, which, together with the glands, was excised and in the fluid from this tumor numerous *echinococcus* hooklets were found. The author comes to the following conclusions. The disease is found only in women; occurs in early adult life; is much more common in married women; is more frequent, apparently, on the right side, and in the upper, outer quadrant. The tumor is at first small, hard, movable, not tender or painful; is rarely multiple; is associated with enlargement of the axillary glands. Occasionally in the late stages the tumor may become large and painful and even fluctuate. The cyst is very apt to undergo degeneration. The diagnosis is difficult, but can be confirmed by means of the exploring needle. Treatment consists in excision, and may necessitate partial amputation of the breast. It is not clearly known how the parasite gains access to the glandular tissue. [J. S.]

5.—Packard and Hand report a case of cretinism which improved rapidly upon thyroid extract. The patient subsequently acquired typhoid fever that ran a rapid and malignant course, terminating in death. At the autopsy, in addition to the changes in the intestines, the thyroid body was found to be present, although greatly reduced in size; the thymus was very large, and the hypophysis cerebri was moderately enlarged considering the age and size of the child. Microscopically the thyroid gland showed a considerable amount of fibrous change; the other tissues were apparently normal. The authors discuss the possibility that cretins are much less susceptible to infectious processes than other children, and in the event of recovery they become much more susceptible than other children. The enlargement of the hypophysis is apparently extremely rare. The persistence of the thyroid gland in cretinism is uncommon. The presence of calcareous infiltration of the wall of the blood vessels in the thyroid is unique. [J. S.]

6.—Carey and Lyon report a case of pneumonia in the course of which the patient developed a pseudomembranous deposit upon all the accessible mucous membranes of the body, extending also into the intestinal tract, but not into the urethra. This was white, rough, and adhered closely to the surface. When torn off it left a raw bleeding surface. Cultures showed nothing but the diplococcus of pneumonia, but in a few cases there was contamination with the staphylococcus pyogenes aureus. They give a very complete analysis of the literature on the subject. Usually these cases are mild and soon recover. The process appears to have been conveyed from one part to the other by the patient's hands. The local treatment is usually rather unsuccessful. Curiously enough in this case, the administration of teaspoonful doses of fresh brewer's yeast caused amelioration, and rather prompt disappearance of all the lesions. This may have been merely coincidental. [J. S.]

7.—Stewart reports the case of a woman of 24, a nurse

by occupation, who after attending a patient with typhoid fever, took charge of one of tuberculosis of the lungs, that lived under very unfavorable hygienic conditions. She developed chills and fever, and enlargement of the spleen. There was no leukocytosis, no Widal reaction; the malarial organism could not be found in the blood, and a diagnosis of tuberculosis was therefore made by exclusion. The patient died after a prolonged illness as a result of progressive emaciation. Towards the end there were some symptoms of meningeal involvement. At the autopsy there was marked tuberculosis of the spleen, and recent acute miliary tuberculosis of the other organs. Stewart regards the case as one of primary splenic tuberculosis. [J. S.]

8.—Smith describes the heart of a turkey which was apparently duplex, consisting of two left auricles and a common right auricle, with parts containing two ventricles each. One of these was very much smaller than the other. Unfortunately the vascular system could not be studied. [J. S.]

VRATCH.

July 14, 1901. (Vol. XXII, No. 25).

1. On the Susceptibility of Domesticated Pigeons to Avian Tuberculosis. B. V. MURZAJEFF.
2. Vasiljeff's Method of Quantitative Determination of Albumin in Urine, and its Shortcomings. A. PH. DRZSEVETSKI.
3. On the Diagnosis of Renal Affections. N. A. MICHAILOFF.
4. A Contribution to the Study of Drug Eruptions. A Case of Diffuse Dermatitis Caused by the Inunction of Mercury (Behrend's Medicamentous Scarlatina). E. A. ARKIN.

1.—Murzajeff gives the following conclusions from a large number of experiments: 1. Domestic pigeons show the highest susceptibility to tuberculosis of fowls, less so to tuberculosis of pheasants, and are insusceptible to tuberculosis of parrots and other birds. 2. Experiments with cultures of tubercle bacilli, irrespective of their source, showed that the susceptibility of pigeons in general is not very great (25%), at all events less than that of guinea pigs. 3. Comparing the susceptibility to avian tuberculosis (25%) with that to human tuberculosis (24%), the difference is practically nil. 4. The virulence of Koch's bacillus is extremely inconstant, and so far we have no data by which we could judge of the possibility of increasing it. [A. R.]

2.—Drzsevetski performed a number of experiments with the view of verifying Vasiljeff's method of determining albumin volumetrically. This method, he claims, received no attention from the medical press, although published in 1896. (The method is given in *Simon's Clinical Diagnosis*. A. R.) By making comparative determinations gravimetrically as well as by the use of Vasiljeff's method, he found that the latter gives results far below those obtained by the former (error from 0.4 to 3 grms. per liter). In looking for the cause of the error, the author found that the fault lies not in the salicyl-sulphonic acid, which precipitates the albumin completely, but in the indicator. The true-yellow (echt-gelb) of commerce is not a pure product, and therefore does not give the characteristic reaction with the free acid after all the albumin has been precipitated. [A. R.]

3.—Michailoff reports two cases of renal disease in which phloridzin was employed for diagnostic purposes. In one there was a renal calculus in the right kidney. Subcutaneous injection of 1 c.c. of 0.5% solution of phloridzin in the gluteal region was made and the right ureter catheterized by means of Casper's instrument. Only 2 hours after the injection did a trace of glucose appear in the urine. In the urine from the left kidney glucose appeared 30 minutes after the injection of phloridzin. In the second case, one of a tumor of the left kidney, no glucose appeared in the urine from the left kidney after the injection of phloridzin, while in the urine from the right kidney glucose was found 1 hour later. In comparing phloridzin with methylene blue, the author remarks that the latter has been employed for some years past, and therefore more thoroughly studied, while the former has only been used since 1900, when it was first employed in Casper's clinic. Methylene blue is eliminated

very slowly, the reaction being evident up to the sixth day, while phloridzin disappears from the urine, normally, within 3 hours after the injection. [A. R.]

4.—Arkin reports the case of a man who showed a marked idiosyncrasy towards mercury. After the inoculation, during a course of specific treatment, he developed a high temperature, vomiting and erythema, the clinical picture closely resembling that of scarlet fever, except for the absence of the characteristic tongue and pharyngitis. The age of the patient was also against scarlet fever. Subsequent developments in the case showed it to be one of a dermatitis due to the mercury. The patient had no stomatitis or affection of the kidneys, the usual signs of mercurial poisoning. [A. R.]

MUENCHENER MEDICINISCHE WOCHENSCHRIFT.

July 2, 1901. (No. 27).

1. A Case of Severe Fragmentation of the Thorax, Terminating in Recovery. HEINEKE.
2. The Treatment of Syphilis by Injections. MAX STERN.
3. Casuistic Contribution to the Knowledge of the Ectogenic and Endogenic Intoxication According to Senator. TIPPEL.
4. Syphilitic Sciatica and Its Treatment. F. MENDEL.
5. A Case of Chronic Ileocecal Invagination. QUADFLIEG.
6. Constipation for 35 Days With Smooth Occlusion of the Intestine. P. OSTERMAIER.
7. A Case of Poisoning by Extract of Felix Max. W. GOTTHILF.
8. The Treatment of Chronic Chorea by Hypnotic Influence. SCHILLING.
9. Twenty-Seven Intra-Cranial Resections of the Trigeminal, and Their Results. F. KRAUSE.

1.—Heineke reports a very extraordinary case. The patient, a man of 39, fell while lifting a barrel weighing 180 lbs., and this rolled upon him. When he recovered consciousness there was severe dyspnea and the respiratory movements were exceedingly painful. The hand placed upon the thorax felt a rough grating, and a harsh crepitation could be heard a short distance from the side. The patient developed pneumonia, the heart grew very weak, and the prognosis appeared to be hopeless. But he gradually improved. On the 27th day of the disease a Röntgen picture was made of the thorax, and 29 fractures of the ribs discovered. These involved both sides, and many of the ribs were fractured in two places. Five and one half months after the accident, with the exception of a slight flattening of the right side, a thickening of the ribs posteriorly on the right side, and some pain on coughing the condition of the patient was very satisfactory. [J. S.]

2.—Stern does not agree with Neumann that relapses almost invariably occur within eight months after the treatment of syphilis with injections of corrosive sublimate. He is in the habit of using the following formula. Corrosive sublimate 1 part (2 parts for men). Boiling water 100 parts. To this is added sodium chloride 3 parts. The mixture is then again boiled and filtered. He reports several cases in which the patients, after the injections, recovered apparently permanently. Injections were always made with very careful antiseptic precautions. They are to be preferred to all other methods of treatment when there is any disease of the skin or the digestive organs that interferes with the administration of mercury in the usual way, and in cases of severe syphilis in which it is important to produce a very rapid effect, and where it is necessary to determine the diagnosis by therapeutic measures. They may also be used in cases where other therapeutic measures have failed, or where variation in treatment is desired. [J. S.]

3.—Tippel reports 2 interesting cases. The first, a woman, during the first puerperal period ate some spoiled liver sausage and had immediately severe pains, discoloration of the skin and vomiting. The stomach contents had a peculiar fatty gangrenous odor. This he regards as exogenous intoxication. In the second case, a child of 6, suddenly became unconscious. There was vigorous spasm of the sphincter ani, but repeated washing of the intestine brought forth a very fetid fluid material, after which the child was relieved. A few days later she was taken sick with measles, and the case is regarded as one of endogen-

ous intoxication, due to the presence of the poison of measles in the system. [J. S.]

4.—Mendel reports three interesting cases of sciatica. The first occurred in a man of 23, three years after infection. He developed severe pain in the left leg, and a tumor upon the right parietal bone which was somewhat elastic. The diagnosis was made of a gumma and syphilitic sciatica. Intra-muscular injections of mercury were made in the region of the sciatic nerve, and the patient rapidly recovered. The second case, a man of 52 had some wasting of the left leg and severe pain in the region of the sciatic nerve; there was also a syphilitic periostitis of the tibia. The same treatment produced rapid cure. The third case, a man of 34, also had severe pain in the left leg 10 years after infection. The treatment was again successful. Mendel calls attention to the frequency with which this form of sciatica occurs, and particularly to the rapidity with which it yields to treatment. The injections are very effective and are less liable to produce any disagreeable complications such as stomatitis. [J. S.]

5.—Quadflieg reports the following curious case. The patient, a man of 28, suddenly developed pain in the abdomen during sleep. On careful diet and treatment the pain disappeared, and in a short time the patient began to eat a full diet. The pains immediately reappeared, and there were signs of intestinal obstruction. These attacks occurred frequently and on each occasion the physician was able to determine the existence of a tumor in the abdomen. He finally decided to operate, and it was found that the ileum and the cecum had become invaginated into the transverse colon. Part could be replaced, but the rest required resection. The patient recovered without complications. This condition occurs most frequently in young persons. The symptoms are usually those of intestinal colic. The course is usually sub-acute or chronic. [J. S.]

6.—Ostermaier reports the case of a girl of 14 who had always suffered from chronic constipation. Finally one attack became very severe, and after eight days, vigorous treatment was employed. This had no effect. The patient gradually developed complete anorexia, and a huge tumor gradually appeared in the left iliac region, reaching to a point above the umbilicus. On the 25th day prolonged lavage of the colon was undertaken. Sixty litres of warm water was used on each occasion. Very profuse evacuations of the bowels occurred, the feces usually being very hard, and finally on the 35th day normal movements were secured. Altogether 1500 litres of warm water were employed. The apparatus consisted of an intestinal catheter of hard rubber, 12 cm. long, with a calibre of about 1 cm. The anterior end was olive-shaped, and had 2 openings each 2 cm. long and 1 cm. broad. The water was poured from a height of 1½ meters, through rubber tubing. A small piece of felt was pressed closely around the anus to prevent the re-flow of water. The duration of each lavage varied considerably. After about ¾ of an hour the colon was usually so distended with water and air that it apparently became paralyzed. [J. S.]

7.—Gotthilf reports the case of a man who had severe headache, then vomiting, and on the second day of the attack suddenly fell unconscious to the ground. When the physician reached his side the pulse was almost imperceptible, the heart sounds feeble, the pupils wide, and the reflexes greatly exaggerated. The patient gradually reacted to stimulation, the cramps disappeared, consciousness was restored, and it was then found that there was no paralysis. It was also discovered that just before the commencement of the attack the patient had taken a remedy for tapeworm. A portion of this was still obtainable and found to consist of the extract of male fern which had evidently produced the poisoning. [J. S.]

8.—Schilling reports a rather interesting case, which he believes indicates that the chorea of Sydenham is really a neurosis. The patient, a girl of 7 years, had been attacked with the disease at the age of 2 as a result of great excitement in the family. The disease showed considerable variation in intensity, always increasing whenever any excitement occurred. The girl was moderately well nourished and developed; there was no anemia; the movements involved particularly, the right side of the face and the left arm. As arsenic had previously been given with little effect, the patient was placed upon antipyrin, and on the first day was hypnotized. As a result of the latter procedure, for the antipyrin was soon discontinued, the patient rapidly improved. All the objective signs disap-

peared entirely, including a slight wasting of the muscles of the right side, and some sensory disturbances. Schilling warmly recommends this treatment in similar cases. [J. S.]

9.—Krause, in continuation of his article, reports the third case death as a result of resection of the trigeminus. The patient, a woman of 60, had the right Gasserian ganglion removed with preservation of the bone in the flap. She recovered rapidly and for 10 days the temperature was normal and the appetite very satisfactory. On the 11th day there were slight mental symptoms and a tendency to sleep, together with a slight elevation of temperature. The wound was opened and found to be entirely normal. However, the cerebrospinal fluid was apparently under considerable pressure. The condition continued to alternate between consciousness, and somnolence; the pulse became more rapid, and death occurred on the 29th day after the operation. No further symptoms of focal brain disease had appeared. Nothing was found in the brain to account for death. Krause also reports some other cases in which death occurred as a result of complications such as influenza or pneumonia. In discussing the operation he mentions several details in the after treatment; among these are the protection of the eye on the side of the operation, which can best be accomplished by washing thoroughly before the operation with boric acid, then protecting it with a watch glass, so that all pressure from bandages is avoided. He does not believe in sewing the lids together, and is not sure that atropine is necessary. Under these circumstances decubitus does not often occur. In one case in which the eye became affected it was cured in spite of the absence of the trophic influence of the trigeminus. The fact that the eye has previously been exposed to injury—as for example, in the case of a miller's wife—seems to make the prognosis somewhat graver. Injuries to other parts of the face, in the anesthetic region often lead to ulceration, but this seems to heal without any apparent difficulty. In a few cases severe mental symptoms occurred. In one, apparently hemorrhage into the right hemisphere had taken place. In conclusion Krause warns against performing the operation in those cases in which the neuralgia was the result of neurasthenia, or other nervous conditions. In one such case in which he permitted himself to be tempted into performing the operation, absolutely no benefit ensued as far as the cessation of complaints on the part of the patient was concerned. On the other hand, it had no bad effects. The paper is still unfinished. [J. S.]

1.—Lenhartz discusses septic endocarditis, of which he has observed 38 cases, with rather chronic symptoms. He believes that all forms of septic endocarditis naturally fall into 2 groups. The first, in which the lesion is merely one of a number of manifestations of the septic process, and the second in which it dominates the whole course of the disease. Of his 38 cases of the latter type, 4 improved; one is still under treatment, and the remaining 33 died. They were, about equally divided between men and women; the majority of cases occurred in early adult life. The distribution of the lesions is rather interesting. The mitral valve was involved in 18 cases; the aortic in 11; the tricuspid in 4; the pulmonary in 2, and in 2 cases there

were aortic and mitral lesions, and in one other case aortic, mitral and tricuspid lesions, that is to say, in 18% of all cases the right heart was involved. In the more acute forms the course of the disease lasted from 4 days to 8 weeks. In the chronic, from 3 to 7 months. In 12 of the cases, valvular disease of the heart had existed previously. The causes of the infection were rather varied. In 7 cases it was injury to the urethra; in 5 cases it followed the puerperium; in 4 cases, specific urethritis; in 5 cases, croupous pneumonia; in 2 cases, sore throat; and in 2 cases disease of the gall bladder. He reports one case, apparently following gonococcus infection, in which complete cure occurred. He also observed a case in which the gonococcus was found post mortem. In an interesting case of endocarditis following pneumonia it was possible to obtain the pneumococci in pure culture from the blood every time it was examined, and the number of colonies increased very rapidly. In 28 of the cases careful bacteriological examination was made. During life the staphylococcus aureus was found 4 times, and the albus once, the lanceolatus 3 times, and the streptococcus 8 times. At the autopsy the staphylococcus aureus was found 3 times, the lanceolatus 3 times, the streptococcus twice, and the gonococcus once. In addition, in all cases in which specific microorganisms had been found in the blood during life, the same microorganisms were found in the body after death. In the chronic cases, bacteriological examinations of the blood were made every 14 days. As the case progressed it was observed that the colonies also increased. Several illustrative cases are given. He also calls attention to the fact that the streptococcus parvus, a particularly small variety, is found more frequently than the ordinary form; Litten, indeed, regards it as the cause of malignant rheumatic endocarditis. Lenhartz, however, does not believe this, because it is not found in rheumatic exudates, and would certainly be easily recognized if it were a causal factor in the production of rheumatism. With regard to the clinical manifestations of the condition, chills, which by many observers are considered a characteristic symptom, do not always occur. [J. S.]

2.—Neumann has performed the concluding series of experiments upon himself, in order to determine to what extent alcohol is capable of replacing nitrogen, or rather of preventing nitrogenous waste. After 40 days of total abstinence, during which he brought himself into a condition of nitrogenous equilibrium, he commenced to accustom himself to alcohol by taking at first very small quantities, which he gradually increased. Smaller quantities of alcohol had no effect upon the nitrogenous elimination. Larger quantities, however, that is, 500 grams or more per day, produced a considerable reduction in the amount of nitrogen excreted, and at the same time there was a very marked excess of nitrogen retained in the system. When the amount of fat in the diet was decreased, while the quantity of alcohol was continued, it was found that the nitrogenous balance was altered unfavorably, showing that fat is more valuable than alcohol in the metabolic processes. Finally the alcohol was discontinued, and an excessive quantity of fat administered, when the nitrogenous balance became again favorable. The figures are as follows: In the first period there was +.06; in the second period, in which small doses of alcohol were given, these figures gradually increased; in the third period in which 500 grms. and more of alcohol were taken the balance was +2.02; in the fourth period in which the fat was reduced the balance was —.21, and in the fifth period when the normal quantity of fat was restored and an additional quantity to replace the alcohol, the figures were 2.42. In conclusion Neumann calls attention to the work of Cloppatt, who has completely confirmed his results. [J. S.]

3.—Behrend records the case of a boy, 15 years of age, suffering from mitral regurgitation. He developed an erythematous eruption on various parts of the body, involving also the mucous membranes. He regards both processes as probably the result of a rheumatic intoxication. Also the case of a man suffering from exudative erythema, and at the same time swelling of the right wrist. The latter was apparently the result of an injury. Finally a third case of the same disease in which there was associated hemorrhagic eruption upon the legs, and the signs of mitral regurgitation—a condition that somewhat resembled purpura rheumatica. [J. S.]

4.—Moeller having found "sana," a mixture of suet and

almond oil, a very inadequate substitute for butter as regards its gastronomic qualities, was impelled to test the statements of its manufacturer regarding its absolute freedom from tubercle bacilli. He obtained 3 positive results in a series of cases, which was more than he obtained from natural butter. He therefore concludes, in view of similar results obtained by other observers, that sana is not free from tubercle bacilli. [J. S.]

5.—Hammesfahr suggests the following installation for operations. The operating room is to be arranged as follows: A cabinet with glass shelves, in the upper part the necessary instruments in the lower part the apparatus for producing anesthesia, and the non-sterilized material for bandages. A long table with a metal top contains a large sterilizer for the instruments, and a gas stove with three tops. Below it contains the sterilized and sterilizable bandaging material. In addition the room should contain an operating table, a steam sterilizer, and several small simple tables of iron for holding various utensils and objects. All the materials that are brought into contact with the work must be boiled just before the operation. Sponges and cat-gut should be discarded altogether and the latter can be replaced by celloidin threads. Ligatures should be employed as little as possible, crushing of the vessels by Peon's instrument being preferable. For the skin sutures a wire of aluminum bronze is most satisfactory. In all septic operations the hands must be protected with rubber gloves. [J. S.]

6.—Breitung reports the case of a fish-bone that penetrated one of the tonsils for a distance of 2 cm. It caused slight discomfort, but could not be detected by inspection. Careful palpation of the tonsil, however, enabled him to detect a slightly projecting end, and the bone was withdrawn with little difficulty. He considers palpation of the throat exceedingly important as a diagnostic measure. [J. S.]

7.—Stieh describes a small apparatus consisting of 2 small bulbs of glass united by a narrow opening in which a small stopper of an alloy with a fixed melting point is placed. A platinum wire runs through the bulbs and the alloy. The upper bulb is filled with water, and as soon as the temperature reaches a sufficient degree, the alloy melts and allows the water to flow into the lower bulb. It can then be determined whether the materials that are being sterilized have been heated to a sufficiently high temperature. [J. S.]

8.—Hammer has devised a small hypodermic syringe with an opening in the upper portion of the barrel. Through this opening, the syringe when the plunger is pulled out to its furthest extent, can be readily filled from a dropping bottle, and when the plunger is pushed in a little way it is again closed. This is of great advantage for the injection of various fluids, when greater quantities must be employed than can be contained in the barrel of an ordinary syringe. It is especially practical in the use of Schleich's method of producing local anesthesia. [J. S.]

9.—Krause, in the concluding portion of his article, gives the clinical histories of 27 cases. In regard to the results, these may be briefly summarized as follows:

1. Woman, 47, returned in 8 months.
2. Man, 62, slight return in a year; pain still bearable after 2 years.
3. Woman, 68, 7 years later slight paresthesia, but no pain.
4. Woman, 48, free until death, 17 months after operation.
5. Man, 55, no relapse after 7 years.
6. Man, 72, death on 6th day.
7. Woman, 70, no relapse after 7 years.
8. Woman, 47, no relapse on the side of operation after 6 years. Slight pain on left side.
9. Woman, 37, no relapse after 5½ years. Slight pain on other side.
10. Woman, 67, no relapse.
11. Woman, 45.
12. Woman, 46, hysterical relapse in one year.
13. Man, 42, no relapse until death in 3 years.
14. Woman, 71.
15. Man, 54, no relapse after 3 years.
16. Man, 30, no relapse after 3 years.
17. Woman, 55, no relapse after 2½ years.
18. Woman, 41, no relapse after 2 years, slight attack of pain on left side.

19. Man, 63.
20. Woman, 59.
21. Woman, 44, no relapse in 7 months.
22. Woman, 58, death 6 years after operation.
23. Woman, 30, no relapse after 7 months.
24. Man, 46, no relapse after 10 months.
25. Woman, 50, no relapse after 7 months.
26. Woman, 65, recent case; so far favorable.
27. Woman, 60, recent case; so far favorable.

In an appendix 2 additional cases are reported, both operated upon in June of this year. Neither case was complicated. [J. S.]

13.—Maass has performed a number of experiments in order to determine the degree to which pressure and tension influence the growth of the bones. For this purpose he selected rabbits, and forced the limbs to grow in an abnormal manner by enclosing them in plaster casts. These were left in position for from 4 to 6 weeks, the animal then killed, and the bones examined. He found that in no case did either hypertrophy or atrophy of the bones occur. A normal tendency to growth was manifested, but the growth occurred in the directions of least resistance. All the changes discovered were readily explained as the results of purely mechanical action. In view of these results he has studied human skeletons that have suffered rachitic alterations in the bones, and he reaches the conclusion that these alterations are also due to mechanical influences interfering with their normal growth and development, such as external agencies, and, particularly in rachitis, an insufficient supply of material necessary for the bone construction. [J. S.]

14.—Engel has studied 5 cases of adhesive glomerulitis, in which he has observed the following interesting results: Cellular infiltration in the capsule is due to epithelial proliferation. It usually assumes the characteristic glandular structure. The source of the proliferation of the connective tissue is difficult to determine. It does not seem to arise from the connective tissue of the capsule itself, but seems to be the result of conversion of the fibrinous exudate of the early stages into true fibrous connective tissue, and is therefore to be regarded as secondary. Whether the glomerulitis is a primary inflammation of the vascular apparatus, or of the epithelial tissue is still an open question, but from the fact that one of the primary changes is a fibrinous exudate in the capsule, and that there is a fibrinous degeneration of the capsular epithelium, there is reason to believe that it is primarily epithelial. [J. S.]

15.—Steinhaus has carefully studied a 5 months' fetus which showed the following deformities: The right forearm was considerably shortened, and attached to the upper arm by a firm web. The forearm contains only one bone, corresponding to the ulnar, which is considerably thickened. The lower end of the humerus is also modified and the olecranon is absent. The thighs are of equal length; the tibiae are entirely rudimentary, and represented only by a small cartilaginous mass. The feet are in an extreme varus position. There is typical rachischisis.

Steinhaus believes that we must consider that the deformities occurred very early in the course of the case, and that they are due to intrauterine pressure. This is rendered more likely by the deformity in the right arm and the presence of rachischisis. [J. L.]

16.—Hecker describes a **paratesticular tumor** which consisted essentially of a mass of nonstriated muscular fibres, very irregularly arranged. He discusses the **liomyomata** of the testicle hitherto described in literature, and reaches the conclusion, that, in some of these cases at least, the process is inflammatory, and characterized by a proliferation of the smooth muscle fibres. The fact that there was extreme proliferation of the blood vessels leads him to suspect that this is not a true tumor formation, especially as the patient had chronic epididymitis. Certain arguments appear to be in favor of the existence of a tumor; it was bilateral, situated at the lower end of the *cavum vaginale* at the left of the vesicle, and the absence of inflammatory processes in the tumor itself. [J. S.]

17.—Hello has studied a number of cases of various forms of **tuberculosis of the joints**. Many of these were studied by serial microscopical sections. He reaches the following conclusions: That beginning inflammation causes increased activity in the growth of the cartilage; more severe inflammation causes destruction of the cartilage, either as a result of injury, contact with the inflammatory focus, or by the immigration of cellular elements. The active agent in the destruction of the cartilage is probably the toxin. The cartilaginous cells and the intracellular substances only act as a result of their disintegration and degenerative proliferation. No transformation of cartilaginous cells into other forms can occur. [J. S.]

18.—Kürpjuweit has performed a number of experiments upon the bones of rats and rabbits, which consist in exposing the bone and irritating it with the cautery or nitrate of silver. After periods the animals are killed and the bones examined. The results show that first there is necrosis, then an active and reactive inflammation with enlargement and proliferation of the cells of the bones, and sometimes these unite, giving rise to cells with 2 and 3 nuclei. After 5 or 6 days there is an active proliferation of tissue and Haversian canals, and the formation of giant cells. The granulation tissue seems to absorb the surrounding bone, and sometimes the cavities open into larger normal cavities. Finally new formation of bone occurs, extending from the medullary cavity. [J. S.]

19.—Grünberg has examined the blood of numerous animals in order to determine the characteristics of the leukocytes found in each. We give the separate results briefly.

FISH.

1. *Scyllium Catulus*:

- (1) Small and large leukocytes with large nucleus, sometimes with, sometimes without, acidophilic granules.
- (2) Large leukocytes with simple, medium-sized nucleus, with or without acidophilic granules.
- (3) Similar leukocytes with irregular and fragmented nucleus and acidophilic granules.
- (4) Multinuclear leukocytes, with granules.
- (5) Degenerated cells. The granules varied in shape in the different cells.

2. *Sirenon Pisciformis*:

- (1) Small leukocytes with large nucleus; without granules.
- (2) Mast cells with 2 nuclei and eosinophilic granules.
- (3) Large leukocytes with medium small fragmented nuclei, without granules.
- (4) Mononuclear leukocytes of various sizes with eosinophilic granules.

AMPHIBIA.

3. *Triton Cristatus*:

- (1) Small mononuclear leukocytes, with large nuclei. Without granules.
- (2) Mononuclear mast cells with basophilic granules.
- (3) Large mononuclear transitional cells, without granules.
- (4) Large leukocytes with fragmented or multiple nuclei, with and without eosinophilic granules.

4. *Rana Temporaria*:

- (1) Mononuclear leukocytes with large nuclei, without granules.

- (2) Mononuclear mast cells with basophilic granules.
- (3) Large mononuclear transitional cells, without granules.
- (4) Mononuclear cells, without granules.

SNAKES.

5. *Lacerta Muralis*:

- (1) Small mononuclear leukocytes without granules.
- (2) Mast cells with one nucleus and basophilic granules.
- (3) Large mononuclear leukocytes and transitional cells without granules.
- (4) Large leukocytes with fragmented or with crystalline and eosinophilic granules.

6. *Typhis Fragilis*:

- (1) Small and large mononuclear leukocytes with very large nuclei and small cell bodies. Without granules.
- (2) Mononuclear leukocytes, with eosinophilic granules.
- (3) Large leukocytes with one or two nuclei; sometimes with, sometimes without, neutrophilic granules.
- (4) Very large mononuclear leukocytes with eosinophilic granules.

7. *Tropidonotus Natrix*:

- (1) Small leukocytes with large nuclei, without granules.
- (2) Mononuclear mast cells with basophilic granules.
- (3) Large mononuclear leukocytes with relatively large nuclei, with or without minute neutrophilic granules.
- (4) Large leukocytes with small nuclei and eosinophilic granules.

8. *Chicken*:

- (1) Small leukocytes with large nuclei, without granules.
- (2) Mast cells with basophilic granules.
- (3) Large leukocytes with large nuclei, without granules.
- (4) Large leukocytes with fragmented or multiple nuclei, and eosinophilic granules.

9. *Sparrow*:

- (1) Small leukocytes with large nuclei, without granules.
- (2) Leukocytes with multiple mast cells, with granules.
- (3) Transitional forms with large round nucleus and without granules.
- (4) Large leukocytes with fragmented or multiple nuclei, and with eosinophilic granules, either crystalline, round, or angular.

In considering these results Grünberg notes that leukocytes with large nucleus and small body are invariably present. They correspond probably to the lymphocytes of the human blood. The transitional forms, and polymorphonuclear cells are also almost invariably present. Cells with multiple nuclei are found in all forms excepting one of the snakes. Cells with true spindle-formed nuclei are exceedingly rare, having been found in only one of the fishes. True basophilic granules are never found. The Gamma granules of the mast cells are, of course, frequently present. Neutrophilic granules are only found among the snakes. The acidophilic granules vary considerably in form, and in their reaction to the various acid stains. It is interesting to note that in one of the fish acidophilic granules were found in the lymphocytes—a hitherto undescribed phenomenon. [J. S.]

20.—Beitzke has found the small spots in the anterior mitral leaflet in 51 out of 72 hearts, and in cases as young as 6 months of age. They always occur upon the ventricular side of the leaflet, at the point of junction of the ventricular wall with the septum. They are usually round, oval or irregular. Occasionally they send projections towards the end of the valve. They apparently never occur in the small leaflet. They are hard, sometimes calcified, resist acids and alkalis, stain black with osmic acid, and often contain calcium salts. Microscopically they show some degeneration of connective tissue fibres, no marked change in the elastic fibres, and in the fresh cases some prolifera-

tion of the cells. The cause appears to be chiefly mechanical injuries due to the situation of the leadlet, and in the majority of cases some alteration in the heart itself. [J. S.]

THE SCOTTISH MEDICAL AND SURGICAL.

August, 1901. (Vol. IX, No. 2).

1. Presidential Address on Modern Advances in the Treatment of the Insane. J. G. HAVELOCK.
2. Clinical Lectures on a Case of Heart Disease and Its Treatment. ALEXANDER JAMES.
3. Notes on Five Years' Medical Work in Lower Bengal. MARY H. SIMSON.
4. Discussion on Alcohol. PROFESSORS WOODHEAD and T. R. FRASER; DRs. CLOUSTON, AFFLECK, W. LESLIE MACKENZIE, JAMES RITCHIE, P. A. YOUNG, FOULIS, WELSH, CHURCH, KERR, BALLANTYNE.

2.—A. James in his article on a Clinical Lecture on a Case of Heart Disease, gives his experience in the use of digitalis and strophanthus: (1) In the compensation failure of aortic regurgitation, and arterial sclerosis and chronic Bright's disease, he usually begins with strophanthus; but if this does not seem to be having a distinctly good effect, he has no hesitation in turning to digitalis. In either case he ordinarily combines those drugs with liq. trinitrinae, or potassium iodide, as being likely to ward off high tension effects. In other valvular lesions and in fatty heart cases, he begins with digitalis; but he has no hesitation in changing to strophanthus, if the effects of digitalis are not satisfactory; (2) When the valve lesion has been due to acute endocarditic processes, he inclines to digitalis; when, on the other hand, it has been due to slow atheromatous changes, he inclines to strophanthus. As a rule, therefore, he begins with digitalis in the young, with strophanthus in the old; (3) When with symptoms of compensation failure the heart's action is rapid, he inclines to digitalis; when it is not rapid or slow, he inclines to strophanthus. Two questions may be asked—first, how long may those drugs be continued; and, second, how do we know if the patient is getting an over-dose? First, as to how long they may be continued with advantage. Here must be remembered the common but rather unphilosophical assertion, that digitalis is cumulative and strophanthus is not. Beyond observing that in nature, with all poisons, as with all nerve irritants, a somewhat cumulative or summing effect can be discerned, the author does not further refer to the pros and cons of this assertion as regards digitalis, because in the doses, in which we employ it for prolonged periods, the risks of any evil cumulative effect are slight. Balfour states that half a liquid ounce of the infusion, or ten minims of the tincture, may be safely administered to an adult every twelve hours without fear of cumulative action, and there is no doubt that patients have taken doses for months, or even years, with advantage, and similarly with strophanthus in corresponding doses. It is, of course, different when large doses are being employed, as, for example, when for a few days, in an urgent heart case, fifteen or twenty minims of the digitalis tincture are given every few hours. This leads, however, to the other question, viz., how do we know if the patient is getting too much of the drug? The main indications of this are believed to be diminution in the quantity of urine, increasing rapidity and irregularity of the pulse, sickness and nausea. [T. M. T.]

WIENER KLINISCHE WOCHENSCHRIFT

July 11, 1901. (XIV Jahrgang, No. 28).

1. Lightning Stroke and Electrical High Tension. S. JELIANEK.
2. The Results of Migraine. MORIZ INFELD.
3. Therapeutic Notes. KONRAD STICHL.
 - 1.—Will be abstracted when concluded.
 - 2.—Infeld reports the case of a woman of 29, who had severe headache since her twelfth year with menstruation, pregnancy, excitement, etc. They begin in the tem-

ples, and as they increase in severity, they move toward the occiput. The attacks last a day, and show no aura, vomiting or other prodromal symptoms. Her mother and sister have migraine. She has borne five children. Right-sided hemiplegia came on suddenly in one of these attacks, but she recovered complete use of the side in two weeks. A month after the hemiplegia, cramps developed in the muscles of the right arm, with exacerbations, ceasing only during sleep. Since this, the headache has appeared less, and the attacks are much less severe. Now the cramps in the arm have disappeared, and the attacks of migraine have returned with all their former severity. Infeld explains the occurrence of the hemiplegia as the effect of thrombosis in the left optic thalamus, near the posterior portion of the internal capsule, due to increased hyperemia and pressure during the attack of migraine. [M. O.]

3.—Stich reports that all cat-gut and silk employed in the Leipzig Surgical Clinic is tested. The diameter, number, and strength are ascertained with the raw thread, the sterilized thread and the sterilized, knotted thread. He explains the preparation of adhesive plaster in strips for surgical dressings and for keeping in hospitals. Finally he describes two maximum thermometers for controlling sterilization, one hour-glass shaped, the other of glass tubes, each of which contains the alloy which melts at the sterilizing temperature. [M. O.]

BOLNITCHNAIA GAZETA BOTKINA.

June 27, 1901. (Vol. XII, No. 26).

1. The Stimuli to the Secretion of the Intestinal Ferment. V. SAVITCH.
2. On the Passage of the Gastric Contents into the Intestine. S. I. LINTVAREFF.
3. The Connection Between Diabetes Mellitus and Insipidus and the Female Generative Organs and Pregnancy. K. K. SCROBANSKI.

1.—Savitch, working under the direction of Prof. Pavloff, observed the conditions which determine the accumulation in the intestine of the ferment described about 1½ years ago by Sehepovalski. This ferment has no action on albumins or fats, its only function being to convert the ferments of the pancreatic juice from an inactive into an active state. The author found that the secretion of this ferment is excited by the pancreatic juice. [A. R.]

2.—Lintvareff found by a series of experiments on dogs that the presence of fat or fat containing substances in the duodenum closes by reflex action the pyloric sphincter for a period varying from 1 to 2½ hours. If the fat is introduced into the stomach it remains indifferent as long as it is there, but begins to exert its inhibitory influence as soon as it enters the duodenum. The rationale of this inhibition is explained as follows: The duodenum permits the passage from the stomach only of as much food as it can digest. The presence of fat, therefore, by subjecting the duodenum to an extra strain, requires that no more food enter as long as the fat is being digested. [A. R.]

3.—Scrobanski draws the following conclusions from an analysis of his own case as well as a number of others recorded in the literature: (1) Diabetes insipidus may in some cases progress without affecting the female generative organs. The patient may become pregnant several times during the course of the disease and be delivered at term of healthy children. (2) In the majority of cases pregnancy acts unfavorably on the diabetes insipidus, which may disappear or become considerably improved after the termination of the pregnancy. (3) Frequently, the diabetes of the pregnant does not become ameliorated after delivery. The thirst and the quantity of urine, which diminish during the first few days of the puerperium, rise again, the general condition of the patient becomes worse and she may die from tuberculosis or other complications. (4) Like diabetes mellitus, diabetes insipidus in the pregnant may appear only during pregnancy and disappear after delivery without leaving a trace. The effect of diabetes insipidus on the generative organs of the non-pregnant woman is not well established. The organs may either become atrophied or, if the disease appears during the period of development, the latter may be retarded. On the other hand, normally functioning organs are frequently met with. The fate of the fetus is also uncertain. Generally, the woman carries to term and is delivered of a healthy child, but the pregnancy may be

interrupted, this taking place, as a rule, during the second half of gestation. If the woman gives birth at term to a healthy child, she may nurse it herself, inasmuch as the quantity and quality of the milk are not affected in diabetes insipidus. [A. It.]

JOURNAL DES PRATICIENS.

July 20, 1901. (15me. Annee, No. 29.)

1. The Diagnosis of Scarlet Fever. G. VARIOT.
2. The Treatment of Puerperal Infection. P. HUDIN.
3. Mushroom Poisoning. V. GILLOT.
4. The Galvanic Current in the Treatment of Blenorrrhagic Arthritis. LOUIS DELHERM.

1.—In scarlet fever the period of invasion is short, the rash rapidly following the angina and the fever. There may be vomiting, vague pains in the limbs, and dysphagia, at first, with high fever. There is always some pharyngitis. But the diagnosis is only made when the rash appears. If any contagion from other cases of scarlet fever is suspected, the child should at once be isolated, even before any eruption develops. But when the eruption joins the angina and fever in 24 to 36 hours, the diagnosis is positive. The rash is first seen in the groin, on the abdomen, thighs, chest, and axillae. In 12 hours the entire body is covered with a confluent erythema, distinctly punctiform in character. The eruption may be counterfeited by various drug rashes, and by a rash which sometimes follows the injection of antitoxin. Malignant scarlatina is rare, difficult to diagnose, and more difficult to treat successfully. [M. O.]

2.—When the diagnosis of puerperal infection is certain, digital curettement should be practiced, one hand in the vagina, the index finger in the uterus, the other hand holding the uterus through the abdominal wall. In this manner, all causes of infection should be removed. An injection of bichloride (1-4000) is then given. Instrumental curettement follows, and a solution of creosote in glycerin (1-4) is applied finally, vaginal irrigation completing the treatment. If much hemorrhage occurs, tampons are left in the vagina and uterus. 12 or 18 hours later, another bichloride injection is given. These procedures should also be carried out whenever there exists a suspicion that puerperal infection might develop. [M. O.]

3.—Gillot reports the histories of poisoning by different mushrooms. In one family four people died from eating the *amanita phalloides*, and five others were very ill; in the other, six persons were made ill by the *amanita muscaria*, but all recovered. These poisonous mushrooms much resemble edible varieties. [M. O.]

4.—Delherm reports 12 cases of blenorrrhagic joint trouble, treated during the acute inflammatory, febrile stage with galvanism. Two cases of arthralgia were cured in from one to two applications; three hydrarthroses, in from two to four applications; an arthritis in a small joint, in one sitting; four cases of moderately severe arthritis in from 6 to 14 applications; and three cases of severe arthritis, of the elbow, knee, and back of the hand, respectively, in two, three and many sittings. This electrical treatment should be begun early; and there are no contra-indications to its use. [M. O.]

ARCHIVES DE MEDECINE DES ENFANTS.

August, 1901. (Volume IV, No. 8.)

1. Acute Primary Pharyngeal Tonsillitis. E. AUSSET and DORION.
2. An Infantile Family Disease. LUIS MORQUIO.
3. The Reduction of the Deformity in Pott's Disease. P. REDARD and P. BEZANCON.
4. A Case of Infantile Scurvy. JULES COMBY.

1.—Ausset and Dorion report 19 cases of acute primary inflammation of the normal pharyngeal tonsil, leaving out those cases with developed adenoids, in which the condition is generally recognized. But it is a fact not universally known that the pharyngeal tonsil can become inflamed, without hypertrophy, just as the palatine tonsils do. Hypertrophied or not, this inflammation has been called adenoiditis. It occurs with most infectious diseases,

and, when it persists, forms adenoids. Or it may be a purely local condition, due to the different septic cocci. Cold is the usual predisposing cause. Its onset is sudden, first a slight coryza appearing, followed by fever and constitutional symptoms. These vary in severity. There is always some dry cough, followed by snoring and mouth breathing. The voice changes and earache develops (noted in eleven out of the nineteen cases), but without otitis media. The cervical glands enlarge, as a rule. Examination with the mirror or the finger confirms the diagnosis. Generally it runs an acute course, with spontaneous recovery in three or four days, or adenoids follow, especially after several attacks of pharyngeal tonsillitis. Antiseptics and menthol are the only drugs used. Ausset and Dorion consider the condition common. [M. O.]

2.—Morquio reports a rare symptom-complex seen in two brothers, aged 8 and 5 years, whose three brothers had died at 8 and 10 years of age, with identical symptoms. In the family history nothing of interest was discovered except that an aunt had had convulsions, and died insane. The eldest brother, aged 17, had never been ill, and the youngest, a child of 2, is also well. In both boys convulsive attacks appeared at four years, as many as five in a day, with or without unconsciousness, generally caused by some emotion, and followed by headache. There was arrhythmia, with an irregular, unequal pulse. The attacks were epileptic and syncopal in character. The elder boy died with influenza. The autopsy showed a persistent hypertrophied thymus, dilatation of the right ventricle and some congestion of the liver and spleen. The other organs were normal. The disease shows the syndrome of Stokes-Adams. Morquio believes the cause of this odd disease is some alteration of the cardio-bulbar centres, with congenital malformation or hereditary weakness. The absence of all lesions tends to confirm this theory. [M. O.]

3.—Redaud and Bezancon describe their routine treatment, by slow forcible extension, of the spinal deformity in Pott's disease. In cases which have existed only a few months the whole deformity disappears in one treatment of from ten to fifteen minutes. Cotton is placed over the reduced deformity and a plaster jacket applied. The child is then left lying on its abdomen, out of doors, as much as possible. As a rule, the deformity should be reduced before it has existed eighteen months. After two years it should be left alone. The results are excellent in Pott's disease of the dorsal and lumbar vertebrae. Of their 60 cases, 14 are well, 29 are pretty well, 12 have paraplegia, abscess or tuberculosis elsewhere, and 3 or 4 have died. [M. O.]

4.—Comby reports a case of infantile scurvy in a child of 11 months, fed upon "lait maternisé." Gaertner's milk, made from cow's milk by removing the casein by precipitation. This boy showed purpura, gingival fungosities and hemorrhage, and multiple subperiosteal hematomas. He was very thin, anemic, and weak. Upon fresh milk, orange juice and mashed potatoes he recovered rapidly. Comby states that of the eleven cases of infantile scurvy published in France, the condition was due to "lait maternisé" in eight cases. [M. O.]

KORRESPONDENZ-BLATT FUER SCHWEIZER AERZTE.

September 1, 1901. Jahr. XXXI, No. 17.

1. A Further Case of Puerperal Gangrene of the Foot. E. WORMSER.
2. The Mechanical Reduction of Bodily Temperature. ERNI.
3. A Contribution to the History of the Treatment of Clubfoot. E. HAGENBACH-BURCKHARDT.

1.—Wormser reports another case of puerperal gangrene of the foot, in which three weeks before parturition a prepatellar bursitis had developed. Pus was found to be present and the fever considerable. In this condition the woman, who was thirty-four years of age and in her sixth pregnancy, was brought into the hospital with two fistulous openings in the knee. She was delivered on the same day and examined but once internally under the precautions of a sterile rubber glove. Bronchitis and diarrhea then set in. Three days after delivery a large foul-smelling clot was removed from the uterus, followed by intrauterine irrigation. The prepatellar abscess was incised and evacuated, quickly healing. The temperature again began to rise and more putrid clots were removed. The uterus was curetted. On the twelfth day after delivery

gangrene began on the left foot, which became more marked on the following day. Death occurred two and one half days later, no time being left for the time of demarcation to set in. The autopsy confirmed the clinical diagnosis of general septicemia due to streptococci, as ascertained by the chill, fever, pulse, articular involvement and the bacteriological findings in the lochia. The postmortem diagnosis of gangrene was based upon thrombosis of various venous radicles in the affected area, there being no involvement of the arterial system, in addition there was found a suppurative of the symphysis. The author unfortunately omitted to examine the pus in the prepatellar abscess, and can therefore not state with certainty whether the streptococci found in the endometrium which were responsible for the general infection originally came from the prepatellar abscess. The patient stated emphatically that she had not been examined outside, and she was but once examined during her labor and that with the aid of a sterile glove. The author states that the gangrene can take place in one of three ways; either by interruption of the venous and articular circulation or by both. The latter is the most common and was present in the first case the author reports; rarer, however is the pure arterial involvement and the rarest of all, the exclusive participation of the venous system as was present in this case. [M. R. D.]

3.—The author refers to **Streckeisen**, who in 1868 was physician at the Childrens' Hospital of Basel. Notwithstanding the author has failed to find this name mentioned in relation to clubfoot within the last thirty years. But later Dr Fritz Miescher, who afterwards became Professor of Physiology, and Dr. Albert Burchardt published in conjunction with Prof. K. Rudmeyer, with the drawings of a skeleton of a clubfoot, the treatise entitled "Notes Concerning the Structure and Treatment of Clubfoot as Taken from the Drawings left by Prof. Streckeisen," and which may be found in the *Jahrbuch für Kinderheilkunde*, Bd. II. [M. R. D.]

PRESSE MEDICALE.

July 24, 1901. (No. 59).

I. Massive Globulinuria.

A. CHAUFFARD and F. X. GOURAUD.

2. The Treatment of Foreign Bodies in the Urethra.

II. HARTMANN.

1.—**Chauffard and Gouraud** report a **unique case of massive globulinuria** in a woman of 29. She had always been delicate, yet never very ill. While always complaining, she has during the past two months noticed slight headache, cramps in her legs, troubles of vision at times, but no other signs of Bright's disease. She weighed about 90 pounds, was very nervous, but only slightly hysterical. She was constipated and had no appetite. A few rales were heard over both lungs, and the arterial tension was much lowered. Her urine was clear and without sediment. Nitric acid and heat showed quantities of albumen at once. But when 5 or 6 drops of acetic acid were added, the urine became a mass of yellow, transparent jelly. It could be inverted without losing a drop of liquid. On milk and arterial tension increased, as did the quantity of urine passed. The urine, chemically examined, showed deficient chlorides. The amount of albumen, at first 50 g. to the liter, rapidly diminished. Cryoscopy, the absence of casts and the low arterial tension show that there was renal insufficiency due to circulatory stasis. From a series of tests they concluded that the albumen found was pure globulin. Its excessive solubility in acetic acid was probably due to the small quantity of chlorides in the urine. That a jelly was formed by the acetic acid and the globulin was due to the immense amount of albumen, to its being all globulin, and to its incomplete solubility in the acetic acid on account of the great amount of globulin present. As the globulin decreased in quantity, the urine failed to jelly. That there was no nephritis is plain. Examination of the blood showed that it was normal. They conclude that this patient had **hyperglobulinemia**, a disease of the blood plasma, with a pathologic deviation from the normal equilibrium of the albumen of the circulation. The symptoms of the condition are globulinuria, hydrochloruria, and arterial hypotension. She was quite well in two weeks. [M. O.]

2.—The treatment of foreign bodies in the urethra depends upon the nature of the foreign body. When certain

that a foreign body exists in the urethra, there are two ways of removing it, through the urethra, or by urethral section. Often by closing the meatus and having the patient urinate, a calculus will be moved. A pin may be treated by performing version, the head being expressed first, or instruments may be introduced to catch the foreign body and remove it through the incision. This should be done and remove it. Finally, when all other methods fail, cut down upon the foreign body and remove it through the incision. This should then be closed again by sutures.

JOURNAL DE MEDECINE DE BORDEAUX.

July 21, 1901. (31me. Année, No. 29.)

1. Lumbar Puncture. JEAN ABADIE.

2. Alterations in the Blood due to the Bites of Venomous Serpents. R. AUCHE and L. VAILLANT.

3. The Treatment of Cataract. BADAL.

4. Facial Paralysis of Dental Origin. H. RODIER.

1.—**Quinke** first performed lumbar puncture in 1890. **Abadie** describes the technique now carried out by **Tuffier** as the best method. He also relates the accidents which may occur with or after lumbar puncture, not as a rule serious. Only small quantities of cerebrospinal fluid should be withdrawn, and that should be allowed to flow slowly. Lumbar puncture is indicated in congenital hydrocephalus, brain tumor with pressure symptoms, meningitis, etc. As a therapeutic measure it has remained worthless, so far as regards recovery. As a palliative proceeding it is very useful. Headache, epilepsy, cerebral tumor, chorea, etc., have all been improved temporarily by it. Lately lumbar puncture has been supplemented by the injection of drugs, especially to produce anesthesia. [M. O.]

2.—From their experiments, **Auché** and **Vallant** conclude that the bites of venomous serpents have the same effect upon the blood as the injection of extract of dried venom. The red corpuscles are destroyed in great numbers, and there is marked leukocytosis, with increase of the polynuclear leukocytes and diminution of the lymphocytes. [M. O.]

3.—**Badal** reports three cases of cataract treated by iodide of potassium and sodium washes. These are applied in a cup for a few minutes, with the eyelids wide open, twice a day. By this treatment he has never seen a cataract disappear, but it fails to progress further and remains stationary. The case-histories follow. [M. O.]

4.—**Rodier** reports a case of facial paralysis in a woman of 23, occurring the day after an alveolar abscess. Neuritis of the trigeminal developed and was transmitted to the facial by its recurrent fibers. The cause was dental caries, and the whole condition disappeared when the tooth in question was extracted. [M. O.]

CENTRALBLATT FUER CHIRURGIE.

July 13, 1901. (28 Jahrgang, No. 28.)

1. The Technique of the Operation for Appendicitis.

SPRENGEL.

1.—**Sprengel** raises the pelvis before operating, and makes his incision along the outer edge of the right rectus muscle. Tampons are then introduced to guard the abdominal and pelvic cavities, and the abscess is opened, with removal of the pus. Should the tampon be soiled by the pus, another is introduced. No irrigation is used unless peritonitis exists. The tampons are removed and the incision is partially closed with silk sutures. Drainage is left in. **Sprengel** wears gloves when he operates during an attack of appendicitis. Since his last report he has operated upon 29 cases, 7 in the interval between attacks, 9 in the first forty-eight hours, with no deaths, and 13 later with four deaths. [M. O.]

Two Cases of Laryngofissure.—In the *Journal des Sciences Médicales de Lille*, (June 22, 1901), Dr. H. Lavynd reports two cases in which laryngofissure was performed. In the first case, a man of 48, with a cancerous ulceration of the larynx, laryngofissure was done with removal of the tumor, a few days after a preliminary tracheotomy. The patient recovered, but a few months later the tumor recurred. Total laryngectomy was then performed, followed by death a week later from broncho-pneumonia. In the second case, a man of 54, with a papillomatous polyp of the larynx, laryngofissure was performed without preliminary tracheotomy, and the tumor removed. He recovered, and his voice again became normal, after employing faradic electricity for the vocal cords. [M. O.]

Society Reports.

MEETING OF THE NEW YORK MEDICAL ASSOCIATION.

The New York Medical Association held its annual meeting in the Academy of Medicine, New York City, October 21, 22, 23, 24, 1901, the first day's sessions being devoted to routine business of an unscientific character.

The regular scientific business of the Association began with the morning session of Tuesday, October 22, 1901.

TUESDAY, OCTOBER 22—A. M. SESSION.

The Association was called to order at 10 A. M., by the President, Dr. John A. Wyeth.

Dr. Irving S. Haynes, Chairman of the Committee of Arrangements, delivered the address of welcome. He said that it afforded him much pleasure to welcome the members of the Association; that the benefits to be derived from the meeting were not only of a scientific nature, but also of a social one, and that he trusted that each would endeavor to promote the feeling of fellowship by being cordial to others. In preparing the program, he had, after consulting with the officers, asked men who had not been on former programs, in order to have all represented. He also had departed from the usual custom and invited the physicians' wives to the annual dinner. He expressed his thanks for the hearty co-operation of all the members in making the arrangements.

The first contribution to the morning's session was that by Dr. Wisner R. Townsend, New York City, entitled, *The Correction of Deformities Following Osteitis of the Knee*. Osteitis of the knee, involving the lower end of the femur or the upper end of the tibia, or both, with or without destruction of the joint, is followed in about 50% of cases by deformity. This should and could be prevented by proper treatment. How to prevent this has been much discussed by surgeons. The author's views do not differ from those of the majority of surgeons, and may be found in an article on "Tuberculosis of the Knee-joint" published in the *Journal of the American Medical Association*, January 12, 1901. The amount of motion following treatment varies. Results as given by Giboney in 300 cases were as follows: 40 died, 14 were excised, 4 were amputated and the remaining 242 were traced. It was found that under the best conditions 95% recovered with motion; under less favorable conditions only 60% recovered with motion. Deformities may be classified under 2 heads: (1) Sub-luxation; (2) All other deformities, which include flexion, bow legs, knock knee, twisting, rotation and anterior displacement of the tibia. The writer advocated osteotomy for correction of all these deformities, and he showed by photographs of cases that even where the angle made by the junction of the upper and the lower leg was 90 deg., it was possible by an osteotomy above the condyles of the femur to make a straight limb. In his opinion excision in these cases was rarely indicated, for the dangers of osteotomy were less, the healing more rapid, there was less sacrifice of tissue, and less danger of starting up new inflammatory processes.

Echinococcus Disease in North America.—Dr. Irving P. Lyon, Buffalo. (Read by title).

Appendix Fistula, John B. Deaver, Philadelphia. Published in full in this issue of the Philadelphia Medical Journal.

TUESDAY, OCTOBER 22—AFTERNOON SESSION.

Symposium on Malignant Growths.

The Clinical Course of Cancers with Reference to Their Resemblance to Inflammatory and Infectious Processes, Dr. Albert E. Wochert, Buffalo. It is doubtful whether there is an infectious cause or not, and, if so, whether of animal or vegetable nature. Environment seems to play some part, as cancer is more frequent in some localities than others. In Buffalo it is about 4 times as frequent in the German and Polish settlements as in those of the native-born. The inhabitants living upon some soils, as the lime stone, it has been claimed, have marked immunity from cancer. Authors differ in regard to the part heredity plays in the causation of it. However, there is no stage of incubation, and the process is local in the beginning. Cases may be divided into 3 groups: (1) Those in which meta-

stasis occurs early and they are rapid in growth; (2) those more chronic in growth and ulcerations may form; (3) those marked by a mild toxemia. Pyrexia is common, if the cancer is of internal origin. If the liver is involved, there are apt to be chills, intermittent in character. In the pyrexia carcinoma resembles tuberculosis. Osler found in some of his cases a temperature of 103°. In six cases of the author's, two of the liver and four of the stomach, he found variations of from two to four degrees. This points to an infectious process. The blood also would indicate this, as there is first mild anemia, becoming more marked later, in this resembling tuberculosis and syphilis. The kidneys show marked change, and may bring about fatal termination by coma. More elaborate clinical studies are necessary to assist the pathologist to establish the nature of the process.

The Present Status of the Infectious Theory of Malignant Neoplasms, George Blumer, Albany. He went carefully over the ground and discussed the question in all its bearings, and while stating that many points were highly suggestive, the following summary gave the real facts: 1. The most careful bacteriological studies had demonstrated no constant organism. 2. The various morphological studies are not agree. 3. Certain facts of distribution were suggestive of the infectious process, but much more extensive observations must be made before definite conclusions could be reached.

The Estimation of the Malignancy of Tumors, with Reference to the Reported Cures of the Disease, Dr. James Ewing, New York. There is great difference of opinion among surgeons as to the curability of cancer, some reporting 40% of cures, while one eminent surgeon said that he had never cured a case. In the opinion of the writer there should be more careful histological classifications of cancer; then it would be possible to make a more reliable prognosis. In cases of epithelioma, which were the least malignant, thorough excision usually resulted in cure, while the pure carcinoma were the most malignant, and in a very short time nodes had usually extended to a serious extent, and there was but little hope of curing these. In all the field there should be greater co-operation between surgeons and pathologists, in order to arrive at a more reliable prognosis of tumors commonly called cancers.

The Treatment of Carcinomatous Growths by Caustics, Dr. Andrew R. Robinson, New York. Whatever the theory as to the origin, all agreed that the diseased tissue must be thoroughly destroyed, in order that a cure might result. In his opinion the cutaneous epithelioma were the only cancers amenable to treatment by caustics. The writer reviewed the use of the various caustics, but gave his own preference to *caustic potash*, which in some cases gives as good results as excision. He also liked the results obtained from *arsenous acid*, and gave it as his opinion that few cases of epithelioma of the face should be treated by the knife.

The Surgical Treatment of Cancer, Dr. Frances W. Murray, New York. (Read by title).

Malignant Disease of the Nose and Accessory Cavities, Dr. Joseph S. Gibb, Philadelphia. The usual form of cancer found upon the septum of the nose was sarcoma, and the symptoms were the same as in all destructive diseases of the nares, epistaxis being a marked symptom, while pain might or might not be. Carcinoma was more frequently found starting from the ethmoid and spheroid cells and spreading rapidly in all directions, characterized by pain and vascularity. In the naso-pharynx of young persons sarcoma is frequently found, while in the accessory sinuses both sarcoma and carcinoma occur. In all these cases of malignant disease the prognosis is bad. Surgical treatment offers the only hope of relief.

Intrathoracic Growths, Dr. Alexander Lambert, New York. He stated that growths occur in the pleura, lungs and mediastinum. Those of the pleura are usually secondary to growths in other parts of the body. In making the diagnosis, the presence or absence of the tubercle bacilli in the pleura is significant. Carcinoma occurs in the lungs more frequently in men than in women, and after middle life. Sarcoma also occurs and may resemble military tuberculosis. The symptoms are dyspnea, pain in the chest, raspberry-juce sputum, fever and emaciation, usually metastasis in

the axilla. Of the tumors of the mediastinum, sarcoma occurs in the anterior and is most marked by circulatory disturbances, while carcinoma occurs in the posterior and is most marked by respiratory disturbances. Pain is a common symptom, cough an early one, and often spasmodic. Dysphagia should always arouse suspicion of an intrathoracic growth; there is usually bulging of the chest. Duration of the disease is from months to years. The treatment is symptomatic.

Cancer of the Large Intestine, Dr. James P. Tuttle, New York. The point of occurrence of cancer of the large intestine is most frequent at the cecum, secondly at the sigmoid flexure; thirdly the hepatic flexure, and fourthly, the splenic flexure. It develops about equally in both sexes. The development as to age is not very definite, but the author believes it is more common in the young than was formerly supposed. It is a question of age in tissue instead of age in years. The symptomatology in the early stage is obscure. In epithelioma the symptoms are largely reflex. In medullary carcinoma there is passage of pus and blood. In scirrhus there is obstinate constipation. The author believes that, if the bowel is kept washed out, there will be no temperature, as it arises from the retained fecal masses. In regard to treatment all local medication is palliative, and there is but little hope from radical treatment, except in the early stage. The author reviewed the various operations for the relief of this disease and the results.

Malignant Disease of the Penis, Dr. Henry H. Morton, Brooklyn. The author said that age was a predisposing cause. It occurred usually after 50 years; phimosis is another cause. The Jews were largely exempt from the disease. It occurred in men of uncleanly habits and men of gouty tendencies. In the diagnosis persistent wart should be considered suspicious; the history will differentiate from syphilis. Death results in from 1-2 years without operation, but in early complete operation the prognosis is very good.

Malignant Disease of the Uterus, Dr. Willard M. Polk, New York. (Read by title).

The Daily Medical Inspection of Schools, Dr. Frederick William Longhran, New York. The essayist said that it was just as much the duty of parents to preserve the health of their children as to educate them. He showed most convincingly the great good which must inevitably follow an intelligent, well-directed system of school-inspection in the saving of life, by early detection of diseases, the prevention of epidemics by the prompt isolation of sick children, and the improved health of pupils by better sanitary regulations in the school building. He appealed to all physicians to become better educated themselves along this line, and then do all in their power to educate the laity in regard to the wisdom of daily school inspection.

The Ethyl-Bromide and Chloride Respectively as Surgical Anesthetics, Dr. S. Ormond Goldman, New York. The doctor exhibited the apparatus for the proper administration of these two drugs. He gave a careful description of their scientific administration and of the action of each upon the body. In his opinion these anesthetics should be used for minor surgical operations, and never for major, as the prolonged administration was dangerous. He also believed they were very useful to begin ether anesthesia.

Perforation of Gastric Ulcer, Dr. Lucius W. Hotchkiss, New York. He reported a case successfully operated upon sixty hours after perforation. The history of the case was negative and the patient was admitted to the hospital, supposed to be suffering from intestinal obstruction, but peritonitis developed, the correct diagnosis was suspected and confirmed by operation. The author described his method of operating, and also stated that about 95% of cases of perforation of the stomach die unless relieved by operative treatment.

Alcohol as a Therapeutic Agent, Dr. Frank Wellington Dennis, Unionville. At the beginning of the 20th century no drug is more ignorantly prescribed, and produces more physical degeneration than alcohol. Physicians should teach the people these evils instead of following them. After carefully reviewing the therapeutic and physiological action of alcohol it is, in his opinion, so dangerous to humanity that other drugs can and should be used instead of it.

Pelvic Inflammations in the Female, Dr. Abraham Brothers, New York. The doctor said that its management by the general practitioner should only continue when the diagnosis

of pus could be excluded. He contrasted the old pathology with the modern ideas of this condition, dealt quite fully with the causes and urged all physicians to watch carefully their patients who are suffering from the so-called pelvic inflammation, for many of these really contain small pus foci, and any over-exertion might start up renewed trouble. The author believes that in all cases of pus formation, the treatment properly ceases to be medical, and becomes surgical.

Skin Diseases of Special Interest, Dr. Grover W. Wende, Buffalo. He gave a very fine stereopticon illustration of these lesions.

MORNING SESSION, OCTOBER 23, 1901.

10 A. M.

Under the symposium of arteriosclerosis, the first paper was by Dr. Charles E. Mack, New York: **Arteriosclerosis; Importance, Definition, Etiology and Symptomatology.**

First considered was the importance of a thorough study of the blood-vessels, their structural and pathological relationship. A man may be actually old at 30, while another may be old at 50, according to the condition of his arteries. Influence of the nervous system on the blood-vessels, as well as heat and cold, is very marked. Pathologic conditions affect the vessels and heart. Arteriosclerosis is a hyalin degeneration and may exist with or without atheroma. The doctor showed a specimen of aneurysm of the innominate artery. Causes: Heredity, age, sex, alcohol, syphilis, gout, rheumatism, and other acute affections, high-living, hard work, psychical emotions, worry and nervous strains. That "a man is as old as his arteries," is true. Preponderance of cases are in men, owing to their occupations and less restful, less quiet lives. Alcohol is a predisposing cause of arteriosclerosis. There is a relationship existing between arteriosclerosis and hypertrophy of the heart.

The death rate of medical men from 1884-1892 was exceeded only by that of saloonkeepers (who are intemperate), by butchers (who are gluttonous), quarry men (who are exposed to explosives), and underpaid factory employees. 35% of physicians die from arteriosclerosis, heart disease and apoplexy. The kidney is affected and sometimes the brain.

Retinal Findings in Disorders of General Nutrition, L. A. W. Alleman, M. D., Brooklyn. (Read by title).

Cardiac Manifestations of Arteriosclerosis, Dr. De Lancey Rochester, Buffalo.

Hypertrophy of the heart muscle, changing to fibroid degeneration, is early noted. Cardiac manifestations are: Hypertrophy with degeneration, degeneration of the myocardium, and angina pectoris. In certain attacks of palpitation, dyspnea and cyanosis he gives hypodermic injections of nitroglycerin and hot mustard foot-baths, followed by morphine and atropin. He advises the hot-air bath and keeping the bowels open. For the arterioles he gives potassium iodid, and for the circulation thiet, nux vomica. Cactus and valerian are likewise given, but he considers digitalis dangerous, because of its action on the arterioles, and he questioned whether it has any place whatever in the treatment of cardiac manifestations in arteriosclerosis. Amyl nitrate is also a good drug.

Management and Therapeutics of Arteriosclerosis, Dr. Egbert Le Fevre, New York.

The essayist took up the question of cardiac failure and its relation to the arterial system. Successful treatment and management depends upon a consideration of all the causes produced. The most important factor in arteriosclerosis is age, and more or less change in the bloodvessels is natural. There are three stages: 1. Toxemia, which constitutes the curative stage. There is arterial spasm, slight pathological changes in the bloodvessels with hypertrophy of the muscular coat, when there is a hereditary tendency, and usually the onset comes on after 45 years. The habits of the patient have a great influence on the disease. The management and treatment of this stage are mainly prophylactic and very important. Exercise in the open air, outdoor life, diet, small amount of meat, but plenty of vegetables, the eating of which should be encouraged. If alcoholic stimulants must be given, they should be limited to whiskey. The early stages of arteriosclerosis in women differ from those in men on account of

the difference in their daily life. Where toxemia is more or less chronic, it may be necessary to take a saline cathartic. A capsule containing quinine is taken in the morning with laxative doses of mineral waters or phosphate of soda. Second stage—capillary fibrosis. Patient feels heart thumping against chest wall, but thinks it only comes from indigestion. The idea is to put off cardiac failure. Increased obstruction of the artery causes increased cardiac power which sends the blood into the arteries with much force, causing traumatism and exciting spasm of the muscular coat of the artery. Iodine and salts have been called the medicine of arteries. Clinical experience has demonstrated that in arteriosclerosis it has the power of lowering the blood pressure and does it without diminishing the force of the cardiac system.

Discussion: Dr. Quimby (N. Y.) did not believe that the fibrous changes are pathological. They are retributive, but protective. Questions of tissue-nutrition form the basis of the story. The rise of tension is reflex. Hypertrophy of the walls of the artery, as well as in the heart, are protective, and fibrosis comes when nutrition of the arterial muscle begins to fail.

Dr. Walsh (N. Y.) believed that many of these cases of arteriosclerosis come to the general practitioner as neurasthenia. Very often there is this tendency to take too much note of symptoms—vague pains in the thorax and symptoms of constriction that are not pre-cordial in character. The doctor was of the opinion that heredity played an important part in arteriosclerosis, and that young men whose fathers die at 45 or 50 should not take up work requiring nerve-strain, worry, undue excitement, etc.

Dr. Stockton spoke of pneumogastric pain and sometimes age, sex, alcohol, syphilis, gout, rheumatism and other symptoms of gastralgia as misleading physicians as to arteriosclerosis. Post-mortem findings showed, in some cases, degeneration of the lower part of the left ventricle with heart rupture.

(To be Continued.)

The Section on Ophthalmology of the College of Physicians of Philadelphia met October 15, 1901, Dr. Wm. Thomson, chairman, presiding. Dr. Charles A. Oliver gave the history of a case of **Blindness from Congenital Deformity of the Occiput**. He considered the case a rare example of the occipital or occipito-parietal type of cranial malformation, in which the configuration of the posterior portion of the head is flattened but slightly curved, extending irregularly upward and forward to meet the frontal protuberance; the most marked ocular signs being sensory in character. Vision in each eye in such cases is nearly or entirely lost; the orbits are shallow, particularly at their postero-mesial parts; the eyeballs are but slightly protruded, somewhat enlarged, and enjoy full freedom of movement; the entire motor apparatus of the exterior of the eyes is in proper working order; the pupils are but slightly oversized; the irides are prompt to light-stimulus, effects for accommodation, and convergence; the ciliary muscles are active; the eyegrounds in every detail of neuronal, vascular and lymph structure appear normal; in fact, the eyeballs with their entire adnexa perform their functions properly. This complexus of symptoms, with its absolute blindness and concomitants of slight globular protrusion, divergence, and rotary nystagmus as the only ocular signs constituted a most remarkable clinical picture. In it is seen a blindness the proving of which necessitates a careful study of every possible direct and indirect ocular detail; a blindness that may be safely assumed to be intracranial in type, and probably cortical in character. In such cases, he thinks, it is fairly certain that there is a healthy receiving material which is properly functioning. The visual cortex is unfortunately of such imperfect development, and of so feeble a functioning and resisting power, that it early loses much of its physiological activity, and sooner or later degenerates into a functionless organ. Dr. G. E. de Schweinitz reported 3 cases of **Relapsing Traumatic Bullous Keratitis**. After referring to the fact that, at longer or shorter periods after the apparent healing of trivial corneal abrasions, the affected eye may become the

seat of irritative phenomena quite out of proportion to the original injury, he classified these phenomena under three heads, relapsing bullous or vesicular keratitis, originally described by Hansen Grut; recurring erosions of the cornea, first recorded by von Arlt; and reëvolving traumatic keratolgia, a name given to the affection by Grandelement. He pointed out that these manifestations represented analogous lesions. In the first case recurring erosions of the cornea were preceded by vesicle formation, the result of a slight abrasion caused by the switch of a horse's tail. The duration of the disease, which was cured by the actual cautery and massage with the yellow oxide of mercury, was 10 months. In the second, recurring erosions of the cornea with intense ciliary neuralgia had resulted from a scratch with a finger-nail. No preceding vesicle formation was detected. Cure was effected by touching the erosion with nitrate of silver and holocain. The duration of the disease was about 7 months. In the third case there was typical relapsing bullous keratitis, probably traumatic in origin. The bullae were unusually large, covering the whole center of the cornea, and cure was effected by incising the blister, removing the epithelial walls, and cauterizing the surface with tincture of iodine, followed, when the irritative phenomena had passed away, by massage with the yellow oxide of mercury. The duration of the disease was about 3 months. The symptoms which call attention to this disease were: almost always on awakening the patient experiences some difficulty in opening the eye, followed, when the lid is raised, by marked foreign body-sensation, decided epiphora, flushing of the eyeball, and sharp neuralgic pain. The attack continues from one-half to several hours, the symptoms then subsiding and the eye being again apparently normal. Careful examination during the continuance of the irritative signs will reveal on the cornea a small ruptured vesicle, or a larger blister or bulla, or sometimes simply an erosion of the superficial epithelium without indication of vesicle or bulla, which has probably disappeared before the examination was made. The abrasion can always be outlined by means of fluorescein. Dr. Risley referred to 4 cases of the affection, in 2 of which the Saemisch operation had been performed for abscess of the cornea. In one case, a young woman nursing her child, there was no history or evidence of injury to the cornea, and he had attended her through three attacks. There were numerous small blebs over the cornea, which burst, leaving points of ulceration. He had secured satisfactory results from an ointment of iodoform and atropia, with application of tincture of iodine to the ulcerated area. Dr. H. F. Hansell exhibited a new form of stationary ophthalmoscope devised by Dr. Walter Thorner, of Berlin, first exhibited at the International Congress in Utrecht in 1899. The points of superiority claimed by the inventor and verified by the practical use of the instrument are the entire absence of reflexes, the brilliant illumination of the eyeground, the magnification of the image, the extent of the field and its adaptability for demonstrating a normal or diseased fundus to the person inexperienced in the use of the ordinary hand ophthalmoscope. For studying the eyeground it has no superior. The details are shown with remarkable clearness, and the proportionately large section of the field under observation at one time affords valuable aid in learning the topographic relation of diseased patches to each other and to the papilla and fovea. The corneal and lenticular reflexes are abolished by the action of prisms, which permit the illumination of only one-half of the pupil, and this method in no way interferes with the illumination of the major portion of the eyeground, the size of the illuminated area depending upon the dilatation of the pupil. Dr. William M. Sweet exhibited the form of sideroscope, devised by Dr. J. Hirschberg, of Berlin, which has given such excellent results in locating iron and steel in the eyeball. The magnetic needle is provided at its center with a small concave mirror, the whole being suspended by a fine silk thread in a tube of glass and brass. The flame of a lamp is condensed by means of a convex lens upon the small mirror, and reflected, greatly enlarged, upon a graduated screen a few feet away. The slightest movement of the magnetic needle when brought close to an eye containing a piece of steel magnified on the screen, the movement being greatest when the magnet point is close to the situation of the metal in the eye. The instrument should prove of value in all cases where Röntgen rays or the giant magnet are not available.

OBSERVATIONS ON THE TREATMENT OF CROUP-
OUS PNEUMONIA.By JAMES C. WILSON, M. D.,
of Philadelphia.Professor of The Practice of Medicine in Jefferson Medical
College.

Nearly half a century ago Trousseau, the greatest clinician of France since Laennec, wrote these words: "Pneumonia is not uniform in character: the forms which it assumes, its greater or less intensity and extent—the influence of the prevailing medical constitution—the personal specialties of the patients in respect of age, sex, temperament and previous health—the disease which may complicate pulmonary inflammation, and the unfavorable conditions which may supervene during its course—all demand particular inquiry on the part of the physician. He must take special account of all of them, for they greatly modify the disease, and are also the source of much diversity in the therapeutic indications."* Since that wise utterance medicine has made an enormous advance. Pathology has become a science of definite facts; bacteriology has not only come into existence, but also has assumed in the brief period of its existence leading importance in etiology, diagnosis and treatment. Therapeutics itself has undergone many revolutions and made some advance, but the facts observed at the bedside remain the same—the chill and high temperature, the stitch in the side and dyspnea, cough and rusty sputum, the short course, the critical defervescence, the rapid convalescence of classic pneumonia are the same now as then. The high mortality in certain localities and years, the comparatively favorable course elsewhere and in other seasons, the resistance manifested in early adult life, the helplessness of the senile, the unfavorable influence of previous disease and alcoholism, the disastrous effects of complications, the fact that croupous pneumonia is the terminal event in many chronic diseases and in most healthy persons of advanced age, and that there are occasional exceptions to all these general statements are familiar and abiding truths. The uniformity of the symptom-complex in well developed frank pneumonia is no less remarkable than the diversity of its manifestations in cases of aberrant type. Our dismay at the sudden death of a youth who has apparently been doing well, in consequence of an extension of the exudate or an overwhelming toxemia, is no less than our delight at the unexpected favorable termination of the attack in an aged person. These facts are not only the cause of much diversity in the therapeutic indications; they are likewise the cause of a most bewildering diversity and perplexity in the therapeutic conclusions. Thus Petrescu, after an experience of thirteen years with enormous doses of infusion of digitalis in a series of 1,192 cases, reported a mortality of 2.66 per cent.—while 500 cases from the recent records of the Pennsylvania Hos-

pital, May, 1897, to August, 1901, treated upon expectant-symptomatic methods, showed 125 deaths—25 per cent.* Are we to conclude from the comparison of these figures that the treatment of pneumonia with large doses of digitalis, which created such excitement when first announced, is so much more efficient than the expectant-symptomatic plan, or that this difference in the result is to be explained by difference in the treatment alone. Let us look at the facts in the light of knowledge of the clinical course of the disease and the mortality under different conditions. The observations of Petrescu were conducted in the Military Hospital upon selected cases—young, strong men in previous good health, living under proper hygienic conditions and free from alcoholism. The cases of the Pennsylvania Hospital occurred in persons of that class who seek such an institution only from necessity, many of whom were actually destitute, others overworked, badly nourished, some in previous poor health, aged, tramps and addicted to alcohol. Of 34 of these cases known to have been drunkards, 23 died—a mortality of 67 per cent. The analysis of the results according to age is especially striking: the largest number of cases, namely, 136, occurred in the third decade of life with 25 deaths—a mortality of 18 per cent.—the smallest number one case in the ninth decade. This case terminated fatally. But the mortality by decades with, however, a decreasing number of cases after the third, was in the fourth decade 26 per cent., in the fifth decade 43 per cent., in the sixth 53 per cent., in the seventh 77 per cent., in the eighth 61 per cent. Among the occupations, 122 of the patients were laborers with 42 deaths—a mortality of 34 per cent., 8 were teamsters with 4 deaths—a mortality of 50 per cent., and 13 stevedores with 6 deaths—a mortality of 46 per cent. The frequency with which teamsters and stevedores are addicted to alcohol is well known, and a large proportion of hospital patients who describe themselves as laborers are given to excesses. Furthermore many of those who follow such occupations suffer from chronic bronchitis, emphysema and forms of myocarditis as the result of habitual exposure and over-exertion. Finally a small proportion of hospital patients are admitted in articulo mortis and a considerable proportion practically moribund. It thus becomes evident that personal factors must to a great extent account for such differences in the mortality rather than treatment alone. In point of fact, Aufrecht saw in 377 cases of pneumonia in patients seeking a hospital from necessity, treated without digitalis, at an age between 5 and 20 years, 11 die—a mortality of 2.64 per cent., and Riessell in 127 persons between 20 and 30 years of age only 2 deaths—a mortality of 1.8 per cent., without digitalis. Pel, of Amsterdam, in a recent article on "The Treatment of Croupous Pneumonia Critically Considered,"** from which I have drawn many of the facts in this paper, concludes that "although the admirers of the digitalis therapy furnish cases of pneumonia which have recovered after large doses of digitalis, they have failed to prove that it was just this heroic use of the remedy which caused the favorable termination."

and adds that it might be maintained with equal right that the pneumonia was cured in spite of these doses.

Croupous pneumonia more than any other disease demands very large series of cases to establish the efficacy of any line of treatment, and since this disease occurs under such varying conditions, each of which modifies alike the course of the attack and the mortality, it demands large series of cases submitted to the same treatment under similar conditions of age, occupation, previous health and the like—conditions not likely to be fulfilled and not yet complied with in any disease except in the bath treatment of enteric fever.

It would appear that 75 per cent. of all cases of pneumonia admitted to hospitals recover and that in selected cases such as occur in military hospitals, namely, healthy young subjects, the death rate is much lower and in limited series of cases may be as low as 2 or 3 per cent. The mortality is also light in private practice. This diversity in the death rate has given rise to false conclusions as to the result of various plans of treatment. Aside from such errors conclusions equally false have been drawn from reasoning by analogy. In a recent authoritative publication* it has been assumed that full doses of mercurials and other germicides may favorably influence the course of the attack by rendering the exudate an unfavorable culture media for the pneumococcus, especially if administered too early. In regard to a specific treatment Pel calls attention to the fact that we only know four infectious diseases in which we are able to meet the casual indication. Malaria we can control by quinine alone; syphilis only by mercury and the iodides; rheumatic fever only by the salicylates or analogous substances; diphtheria only by its antitoxine. It would be a remarkable fact if croupous pneumonia—a disease due to a specific micro-organism, should yield to treatment by a number of different drugs selected to meet the cause, as the salicylates, iodides, quinine, mercury, creosote and carbolic acid. Nor does it seem desirable to repeat the futile experiments already made in regard to pulmonary tuberculosis, scarlet fever and other acute infections. The effect of indifferent antiseptics and germicides upon parasitic micro-organisms must bear a definite relation to the mass of the circulating blood in which they are diluted and which may be roughly estimated as from 12 to 14 pints in the adult. Experience has shown in regard to these drugs that the parasite is fully as tolerant of their action if not more so than the host. The dictum of Talamon in regard to tartar emetic holds good for other poisonous drugs: By their use we diminish the prospect of cure since we complicate the disease with the effects of a poison. With specifics like quinine in malaria the case is wholly different. In croupous pneumonia it is probable that the pathological process is fully established upon the occurrence of the chill and that the pulmonary lesion is far advanced before a positive diagnosis can be made. The pneumo-toxines produce the initial chills, the fever and the prostration.

Aufrecht's advocacy of quinine* has recently excited much interest. This observer's statistics, ex-

tending over a period of ten years, show that during the last two years under quinine treatment the mortality fell to 6.6 and 8.2 per cent., although in former years it fluctuated between 9.8 and 25.3 per cent. and even grew to 24.9 per cent. during the year that preceded the quinine therapy.

As Pel has shown, the favorable effect of the use of such drugs as indicated by the mortality statistics is more apparent than real, since wide variations in short series of cases are constantly encountered. This critic calls attention to the fact that the period of observation—two years—is much too short and that the figures are much too small to justify conclusions in regard to the efficacy of a mode of treatment. Nevertheless, notwithstanding these objections, it must be conceded that thoughtful researches in the direction of specifics are justifiable.

Clinical experiments with antipneumococcus serum have not yielded satisfactory results. My own observations in the German Hospital with 36 cases treated with antipneumococcus serum showed 10 deaths—a mortality of 28 per cent. The collected cases of Tyler, of Denver, combined with my own number, 162, of which 135 recovered and 27 died—a mortality of 16.6 per cent. Our observations in the service of the German Hospital have not encouraged us to continue the treatment of croupous pneumonia by the use of antipneumococcus serum. Nor have our experiences with hydro-therapy been more satisfactory. This method of treatment was instituted some years ago upon a series of selected cases. Neither the effects upon the immediate course of the disease nor upon the mortality were such as to justify its continuance. Statements occasionally made to the effect that quinine with aconite or veratrum viride employed before consolidation has taken place "has the power of so modifying the hyperemia in the affected area as practically to abort the local process and prevent exudation" are mere assumptions, wholly without the support of statistical or other facts. There are those who appear to believe that croupous pneumonia can be aborted by various forms of treatment. During the first half of the nineteenth century the denial of the efficacy of abstracting blood in pneumonia would have seemed to the majority of practitioners of medicine the denial of a demonstration. At the present time there are those to whom the denial of the efficacy of calomel, quinine, cardiac depressants and the like arouses the taunt of therapeutic nihilism. But their number is few. The great majority of practitioners at this time advocate an expectant-symptomatic method of treatment. This was the plan advocated by Dietl, Niemeyer, Bourgeois and other leaders of the reaction against indiscriminate venesection. It was practically the plan taught by Flint. It is advocated by Pye-Smith in the admirable article on pneumonia in Allbutt's System, who says: "In the long run the expectant method of treatment, which interferes only as occasion requires, is followed by a far lower mortality than misplaced attempts to jugulate the disease or than a completely negative treatment." Osler says: "Pneumonia is a

* Twentieth Century Practice, Vol. xvi.

** Nothnagel's System, xlv Band.

self-limited disease which can neither be aborted nor cut short by any known means at our command," and again, "There is no specific treatment for pneumonia. The young practitioner may bear in mind that patients are more often damaged than helped by the promiscuous drugging which is still only too prevalent," and Pel, to whose article I have so often referred: "The less the physician interferes with the normal course of pneumonia, the greater the probability of a favorable termination."

The plan pursued in my service at the German Hospital in Philadelphia may be briefly outlined as follows:

The diet consists chiefly of milk and light broths. Junket, custard and like gruels are given if the patient cares to take them. In private practice a little ice cream and sometimes raw or stewed fruits may be given. Grapes are often acceptable. All these things are given in small amounts. If the patient will take from one to two pints of milk and a pint of chicken or mutton broth each twenty-four hours it is regarded as sufficient. Water is given in abundance, not more than 2 ounces at any one time. Under ordinary circumstances the patient is sponged night and morning with water, the temperature of which is regulated by his sensations. If the temperature exceed 104° F., cold sponging may be repeated at intervals of two or three hours. Early in the course of the attack two or three large, flat ice-bags are applied to the affected side. These to some extent relieve pain and make the patient feel more comfortable. They have a slight effect in reducing the temperature, but none whatever upon the extension of the exudate or the course of the attack. Alcohol is given in a majority of the cases. Ordinarily the amount does not exceed four or six ounces of whiskey in twenty-four hours. Larger quantities are given to those accustomed to its use.

A calomel purge is commonly administered at the time of the admission of the patient to the ward. If there be nausea and vomiting calomel is given in fractional doses. In the absence of these a single laxative dose is administered. If necessary, a saline is subsequently given. The calomel is frequently repeated once or twice during the course of the attack. If there be great pain, morphia is administered hypodermically. In any case Dover's powder, usually in the form of tablets of two or three grains, is administered every two or three hours throughout the greater part of the course of the attack. The dose of this medicine is so regulated as to produce a slight continuous drowsiness, from which the patient may, however, be readily aroused. By this means suffering is diminished, cough is to some extent controlled and the excitement and apprehension common in pneumonia allayed. No evil effects have been attributed to this use of opium. Toward the close of the attack Dover's powder is given with diminishing frequency. Expectorants are rarely employed. Fresh aromatic spirit of ammonia and the ammonium carbonate are sometimes given. If they do no good, they have never appeared to do harm. Aconite and veratrum viride are never given, and digitalis only in response to particular indications. If the pulse becomes small and frequent, especially if it becomes irregular, digitalis is sometimes given in full doses, not because the patient is suffering

from pneumonia, but on account of the condition of the heart. In many cases strophanthus has answered a better purpose. As a rule strychnia is given as a cardiac stimulant and the nitrites, especially nitroglycerine, for the relief of the laboring right ventricle. These measures failing with increasing signs of failure of the right heart, the development of small mucous rales and cyanosis, venesection is practiced. If pulmonary edema occurs, atropine is given hypodermically and many times has seemed to avert the fatal issue. Dyspnea is regarded as an indication for the use of oxygen, care being taken that in the administration it is freely diluted with air. Nervous symptoms and delirium are to some extent controlled by the systematic administration of Dover's powder. They demand an increase in the quantity of alcohol. Ice to the head, cold sponging or the cold pack are useful, and in young robust individuals delirium tending to pass into coma is treated by cold effusions to the head and neck, repeated at intervals of three or four hours. These are often followed by marked improvement. Neither poultices nor cotton jackets are allowed. The patients wear a moderately heavy, loose-fitting merino undershirt. Blisters are not used save in the case of delayed resolution, when a series of small flying blisters is sometimes applied. At the crisis the patient is carefully watched. If the Dovers powder has been discontinued, a hypodermic injection or an opium suppository is administered. In some cases ammonium carbonate, alcohol or hot coffee appears to be indicated. Collapse is very rare. During convalescence an abundant nutritious diet is given. The patient is permitted to have meat as soon as he desires it. Bitter tonics are employed in some cases and we are in no great haste to yield to the patient's wish to get out of bed.

I do not speak of the treatment of complications. The prognosis of pneumonia in ordinary hospital cases must always be guarded. The statistics of the German Hospital under this plan of treatment are not satisfactory; the figures for the last five years are as follows:

	No. of cases treated.	Deaths.	Per Cent.
1896	12	7	58.3
1897	48	13	27.0
1898	36	18	50.0
1899	48	21	43.75
1900	42	9	21.43
<hr/>			
Total	188	68	36.56

But on the occasions in which we abandoned it for systematic cold bathing and serum therapy our results were still less satisfactory.

These figures do not indicate the result of treatment but show the intractable character of the cases admitted to the service, the high mortality of the disease in a general hospital and the great variation in the mortality in short series of cases in different years.

APPENDICEAL FISTULA.

By JOHN B. DEEVER, M. D.,

of Philadelphia.

Surgeon in Chief of the German Hospital.

There are two reasons why this subject is worthy of our attention, indeed, it is a subject of the utmost importance, for in practically all instances it is a preventable sequel to operations for acute appendicitis and is only seen in the neglected cases, if procrastination on the part of the physician can be so called. If all cases of appendicitis were operated in the early hours of the attack, this complication would be practically unknown. Secondly, the difficulties and dangers of the operation for the relief of appendiceal fistula are often greater than was the original operation, and much more dangerous than is the operation for the removal of the appendix in the early hours of an attack.

When we consider that there are members of the profession, happily each day becoming less numerous, who still advocate the dangerous policy of delay and the medical treatment of appendicitis, it is not strange that we still meet this sequel with distressing frequency.

The mortality of operation for appendiceal fistula is fortunately not high. Although many brilliant results are reported, nevertheless failure to obtain a cure may result. I fear we are all more tempted to report our fortunate results than those which have an unfavorable termination. This fact, although serving the useful object of stimulating us with greater courage in facing serious surgical problems, also has the disadvantage of tending to make us less thoughtful of their dangers. The man who is continually calling to our notice the dangers and gloomy side of any operative procedure exposes himself to the stigma of retarding the science of surgery. This, however, does not apply in this instance because it not only points out the condition, the cause and means of prevention of which are obvious and after all, "Prevention is the best cure." In the early operation for appendicitis we have the almost certain means of avoiding this complication.

Were operation done before inflammation had occurred, while the condition is still one of appendiceal colic the surgical outlook would be ideal.

Appendiceal fistula occurs as one of two varieties—the external and the internal. In the internal variety the channel of the communication, or the fistula, is in direct communication with some hollow abdominal viscus, or in the case of evacuation of an appendiceal abscess by way of the bronchus with the chest cavity.

In the internal variety any of the hollow abdominal viscera may be involved—any portion of the intestinal tract, the bladder, the dilated portion of the ureter, etc., in fact, any of the viscera in close proximity to the appendix.

These internal fistulae, although numbers of cases have been reported, are quite rare in comparison to the external variety. Fortunately, too, they rarely need surgical interference, as they usually

either heal spontaneously or may remain innocuous, as for instance, a communication between the ileum and cecum. We cannot be sure, however, that these internal bowel communications will remain innocuous. In too many instances not only do they occasion local discomfort and attacks of aggravated intestinal indigestion, but offer a fertile cause for mechanical intestinal obstruction. Further, I believe that the local foci of irritation are in a certain percentage of cases forerunners of subsequent malignant growth.

The least dangerous of these internal fistulae are those in which an abscess ruptures into the cecum, the colon or the rectum, as in this variety the danger of intestinal obstruction is minimized and the discharge of pus by this route the safest. The internal variety of fistula rarely requires operative interference and for this reason is considered by some to be a fortunate termination of appendiceal abscess, this, however, is an opinion to which I cannot subscribe, for I have seen too many unfortunate and distressing consequences follow the adoption of this type of procrastination, and a fatal result in more than one instance compels me to lay stress on these facts. Those cases which terminated fatally resulted from, in one instance a communication with the bladder; a second with a communication with the respiratory system; in a third the communication was with the dilated portion of the ureter. Again, the inflammatory bands around such an internal fistula have caused death by internal obstruction of the bowel from a coil of intestine becoming imprisoned beneath such adhesions.

The external fistulae are much more common, but occur practically always in cases where abscess has been present, or where a gangrenous appendix has rested upon the bowel and by contiguity caused a perforative gangrene of the bowel. This was the case with a famous surgeon of my own city. At the time of operation a gangrenous appendix was found with its tip resting against the bowel. At this point there was a small oval patch of gangrene which several days after operation broke down and formed a very obstinate fecal fistula.

Probably the most satisfactory classification of this embarrassing sequela is that which depends upon the character of the discharge. The discharge from an appendiceal fistula can be divided into the fecal and non-fecal. The non-fecal discharges are urine, mucus, flatus, pus and bile. Urinary fistulae are rare and are practically always due to injuries to the bladder, as the ureters from their anatomical position are rarely involved. Yet the ureter as it crosses the psoas muscle may be injured, I have seen the ureter exposed, when it did not look unlike the appendix stripped of its serous coat. The injuries to the bladder consist either in tears made in freeing adhesions at the time of operation; or are due to ulceration into the bladder, either from the pressure of an abscess in the pelvis, or from an appendix adherent to the bladder. Very occasionally an appendiceal abscess works its way upward and ulcerates into the gall bladder and when this abscess is opened, a true biliary fistula is established. This is for anatomical reasons extremely unusual. Another way in which I have seen a biliary fistula is from an infection of the gall bladder

* Read Oct. 22, at the Academy of Medicine N. Y., N. Y. State Association.

secondary to a non-suppurating appendicitis or, rather, an appendicitis without periappendicular suppuration. After operation the gall bladder has perforated and discharged through the appendiceal wound, the general peritoneal cavity being shut off by adhesions.

The other non-fecal fistulae are always due to the presence of a foreign body, this foreign body may consist of one of several things.

An appendix left *in situ*. In many cases of appendicitis in which the operator contents himself by merely opening and draining the abscess, the appendix itself is left as a foreign body and keeps open a fistula which will not disappear until the appendix has entirely sloughed away or has been removed, usually the latter. In these cases the discharge may be almost pure mucus, and in any case in which mucus is discharged from an appendiceal fistula, we can be sure that all, or part, of the appendix is in communication with the tract. In operating upon such cases I have never failed to find a portion of the appendix and, indeed, in cases in which an abscess has been drained and the appendix left undisturbed, at a subsequent operation, I have always found the appendix to be present. The disappearance by sloughing of such an appendix would be a fortunate occurrence and may occur in rare instances, but personally I have never met with it. Again, a mass of lymph, a part of the wall of the appendiceal abscess, may serve as a foreign body.

An infected suture or a few threads of gauze torn from the drainage are often at the bottom of one of these cases of fistula, in others the only way in which they can be explained is a microscopic communication with the bowel through which only enough fecal matter or gas can pass to keep the sinus open and not enough to give a decided fecal character to the discharge.

The fecal fistulae may be divided according to the part of the bowel in which they occur, in the small bowel, high up or low down, or in the large bowel. Another way, in which they can be divided, depends upon whether all or only part of the feces are discharged through the fistula. When all of the feces escape through the fistulous orifice of communication with the large bowel we have formed, for all practical purposes, an artificial anus. Fecal fistulae involving the upper part of the small bowel can be differentiated from those situated low down in the small bowel by the pronounced biliary character of the discharge and the discharge of liquids from the fistula immediately after their ingestion, in the former the biliary discharge excoriates the skin and forms one of the most embarrassing varieties of fistula with which to deal. This is so pronounced in some cases and the pain so great as of itself to indicate operation for the repair of the fistula.

More solid feces show that the discharge comes from the large bowel. Fecal fistulae of the large bowel are more likely to heal spontaneously than those of the small bowel.

The causes of fecal fistula may be specifically divided into the following:

First.—Slipping or sloughing of a ligature used to ligate the stump of the appendix, one or the other of these accidents may occur no matter what

method is used to close the wound in the cecum caused by the removal of the appendix, for even if the cecum be repaired by several rows of Lembert sutures, infection of these sutures may cause enough sloughing to open a large fistula in the cecum. This variety of fistula may appear immediately after operation or even ten days or two weeks later.

Second.—Sloughing of an appendix left *in situ* may cause an especially bad fistula, as here there is not only the opening into the bowel, but also the appendix remaining as a foreign body.

Third.—Ulceration into the bowel at the point of adhesion of an inflamed appendix. This is an effort of nature to relieve trouble by drainage of the appendix into the bowel, removal of the appendix leaves the opening in the bowel which may be overlooked.

Fourth.—Pressure necrosis of the bowel from an abscess or from the pressure of a drainage tube or gauze left in at the time of operation.

Fifth.—Necrosis of the bowel from interference with its nutritive blood supply either from pressure on the mesentery or from septic emboli in the mesenteric veins. Fistulae due to this cause are most common in the cecum or ascending colon. This accounts also for many deaths from absorption of septic material.

Sixth.—Tearing the softened bowel in freeing adhesions at the time of operation.

Seventh.—Stripping the serous coat from the bowel in freeing adhesions. This is a very common cause of fistula and one which we must always be upon our guard against, most of the nutrition of the bowel is derived from the serous coat and stripping this off usually causes a necrosis of the underlying bowel.

The symptoms of fecal fistula are from the nature of the trouble perfectly obvious, there is, however, for the first three or four days before and after a fistula appears usually a very high temperature. Fecal fistulae may appear in the first few days after operation, but more commonly seven to ten days later, and their appearance at a still later date is not unusual.

The constitutional effects of a fecal fistula are marked by a progressive loss of flesh and strength and impairment of nutrition, owing to the escape of the contents of the bowel containing the elements required for nutrition, in fistula involving the bowel high up in the small intestine, or from absorption of septic material along the tract.

The proper treatment of an appendiceal fistula depends upon whether the fistula is fecal or non-fecal. If it is non-fecal, a careful search should be made for the offending foreign body, as its removal will promptly cause the tract to close; great care should be used in this search not to make a non-fecal fistula a fecal one by traumatism to the bowel.

A great many appendiceal fistulae heal spontaneously and an opportunity should always be given nature to achieve this result, and operation only undertaken after this has failed. The only exception to this rule is a case, in which the fistula is so far up in the small bowel that the nutrition of the patient is seriously interfered with.

As soon as a fecal fistula appears, all drainage

should be removed, the tract should not be washed out or packed, and only the external surface be cleaned, nutrition should be given in concentrated form and every effort made to make the feces as solid as possible, which favors the healing of the fistula. Purgatives should not be given, as a rule, but bowels opened by enemata, which should not be large enough to regurgitate through the wound.

In non-fecal fistula all that is required in the way of operation is a removal of the offending foreign body, which should be done very thoroughly and the tract packed and allowed to heal by granulation from the bottom. When the fistula or sinus communicates with an unhealed abscess cavity, the mouth of the fistula should be enlarged sufficiently to permit of a thorough cleansing and packing. When possible, without opening the general peritoneal cavity, the mouth of the cavity should be enlarged sufficiently to make it equal the transverse diameter of the abscess cavity at its widest part. The urinary fistula of course must be freely exposed and the wall of the bladder repaired, best perhaps by Lembert sutures.

Operation for fecal fistula is a much more serious matter, as the danger of peritonitis from an infection of the general peritoneal cavity is very great. This is best avoided by cutting wide of the fistula and working towards it, carefully isolating the infected bowel by sterile gauze.

Fistula of the small bowel usually requires resection, as a simple repair, if the wound was extensive, would probably reduce the calibre of the bowel to a dangerous extent, and the bowel involved is often in so unhealthy a condition that sloughing would be likely to follow. My preference in this work is for an end-to-end anastomosis without mechanical appliances.

Fistula of the large bowel may either be resected or repaired, according to the judgment of the operator in each particular case. In some instances, in which the cecum has been very much injured, it may be wise to do a lateral anastomosis between the colon and the ileum. This anastomosis may be done either with the Murphy button or needle and thread alone, according to the fancy of the operator. Should a resection of the large bowel be necessary my preference is for an end to end union with needle and thread alone.

If all the feces have been passed by the fistula, the terminal portion of the bowel should be carefully examined to see that it is free from obstruction. Another point that we must be particularly on our guard against is the existence of more than one opening into the bowel, for the overlooking of a second fistula has often rendered unavailing an otherwise brilliant operation.

In regard to drainage after these operations, I will say that it is usually required, although sometimes they can be closed without it, which I prefer when possible. The necessity for drainage depends both upon the amount of inflammatory exudate around the fistulous tract and upon the state of the bowel.

In concluding my remarks upon this distressing sequel to operations for appendicitis, I should like to again lay special emphasis on one single fact, the importance and necessity for an early recognition

of acute appendicitis and its natural corollary the prompt institution of surgical interference. If the appendix is removed before any periappendiceal involvement or impairment of the structures contiguous to the diseased appendix has occurred, then it is well nigh impossible for abscess to occur, except as a result of contamination through a defect in the asepsis of the operative technique. If this is true, then we can avoid the formation of the products of the inflammatory process, prevent invasion of the intestinal walls, make it necessary to have such extensive manipulation as is required in the advanced cases, lessen the number of adhesions to be broken up and leave the field of operation in practically as good a condition as it was prior to the attack of appendicitis.

THE ETIOLOGICAL POTENCY OF HEREDITY IN MENTAL DISEASE.*

By CARLOS F. MacDONALD, A. M., M. D.,
of New York.

Professor of Mental Diseases and Medical Jurisprudence in the University and Bellevue Hospital Medical College; Ex-President of the New York State Commission in Lunacy.

"Heredity," says Ribot, "is that biological law by which all beings tend to repeat themselves in their descendants: it is for the species what personal identity is for the individual. By it a ground work remains unchanged amid incessant variations; by it Nature ever copies and imitates herself."

"Hereditary transmission," says Spencer, "displayed alike in all the plants we cultivate, in all the animals we breed, and in the human race, applies not only to physical but to psychical peculiarities."

The ancient proverb that "when the fathers have eaten sour grapes the children's teeth are set on edge" doubtless originated in a recognition of the important part which heredity plays in the development of human affairs. "There is a destiny made for a man by his ancestors," says Mandsley, and no one can elude, were he able to attempt it, the tyranny of his organization."

In truth it may be said that the transmission from parents to offspring of both physical and mental qualities is a fact of universal observations, and that heredity is of far greater potency than environment in shaping a man's destiny in life. Under and by virtue of the operation of this law of nature we constantly see instances of men of obscure and humble origin, who, despite the most adverse conditions of environment, rise and take their places among the rulers of the nation. Striking confirmations of this law are furnished by the lives of Lincoln, Garfield and the lamented McKinley.

"Bless not thyself only," says the author of the *Religio Medici*, "that thou wert born in Athens; but among thy multiplied acknowledgments, lift up one hand to heaven that thou wert born of honest parents, that modesty, humility and veracity, lay in the same egg and came into the world with thee." On the other hand the heredity of morbid tendencies has been recognized "in all times, in every land

* Read before the Medical Society of the State of New York, at its semi-annual meeting, in New York City, October 16, 1901.

and in every nation," almost from the foundation of the science and art of medicine. The idea of hereditary disease found apt expression in the ancient but familiar declaration that the sins of the father shall be visited upon the children even unto the third and fourth generations.

The term heredity as applied to the study of mental disease—the term mental disease being here used in its broadest sense, that is, to include not only insanity proper but all other psychoses, as idiocy, imbecility and psychopathic states of whatever form or nature—implies an original predisposition to the disease transmitted to children from their parents; and while it is true that insanity resulting from hereditary weakness of the nervous system alone without any apparent exciting cause, is comparatively rare, all competent authorities agree that the hereditary nature of insanity has long been recognized as an established fact in medical science, and that heredity plays a most important part in the etiology of this disease through its actual or potential influence upon the nervous organization, whether the tendency descend from direct or collateral branches of the family tree.

This influence usually manifests itself in the progeny in one of three ways; namely, 1, by congenital absence of mind, (idiocy); 2, arrest of mental development in early life before full mental power has been attained, (imbecility); or, 3, the development of a psychoneurotic temperament or insane diathesis which expresses itself in a defective or unstable nervous or mental organization which in turn predisposes the individual to succumb to circumstances in the nature of so-called exciting causes that would not affect a person of innate stable constitution. That is to say, if an individual having a strong hereditary predisposition to insanity and another who inherits no such tendency be subjected to the same or to substantially similar exciting causes, as, for instance, domestic afflictions, loss of fortune, severe mental strain and worry, ill-health, child-birth, dissipations, excesses, etc., the former would be likely to suffer a mental breakdown, whereas the latter would not; and while it is true in respect to the transmission of psychopathic tendencies that the ancestral taint may be, and frequently is, transformed in the progeny so as to appear in an entirely different form, or it may remain dormant in the second generation to reappear in a later one, or it may be deflected from the direct line of descent to a collateral branch, it is destined to crop out from time to time in one form or another, until it is finally rendered inert through the attenuating influence of wise intermarriages, or until the family becomes extinct through the sterilizing effect of degenerative processes going on through generations.

"He who inherits a predisposition to insanity," says Mandsley, "does not necessarily get it from a parent who happens to be insane—no, not even though his father was insane when he was begotten, or though in madness his mother conceived him. He gets it from where his parent got it—from the insane strain in the family stock."

Unfortunately, in the present state of our knowledge, the *modus operandi* of hereditary action is not

definitely determined. But we do know to a certainty that the effect of hereditary influence upon the individual is to render his brain inherently unstable, and thereby susceptible to influence, in the nature of so-called exciting causes which would be quite inoperative in individuals of inherent brain stability. In fact, experience has amply shown that the progeny of insane or neurotic ancestry are distinctly more liable to develop mental disease under the ordinary conditions of life, than are individuals whose ancestry is devoid of insane or neurotic taint.

An examination, even cursorily, of the published statistics relative to the etiology of insanity, will show them to be of small value, owing to the divergent views of collectors respecting the etiological importance of heredity in mental disease and also to the great difficulty of obtaining reliable data as to the heredity of families, the friends of insane patients being reluctant, usually, to admit, even to themselves, the existence in the family stock of a psychoneurotic strain. According to the statistical tables contained in the official reports of hospitals for the insane, the percentage of cases ascribed to hereditary influences varies from 25 to 90, the average for all countries being about 60 per cent. The conclusion to be drawn from these statistics, if accepted, would lead us to greatly underrate the importance of heredity as an etiological factor, whereas the fact is, its importance could scarcely be overrated. In other words, heredity is by far the most important factor with which we have to deal in any consideration of the causation of insanity.

"The tendency of late years," says Mercier, "has been to lay increasing emphasis upon the hereditary factor in the production of insanity, but it is doubtful whether, even yet, the true bearing and significance of this factor have been recognized." Another recent writer* on mental diseases, referring to predisposition, says: "This tendency, although it may sometimes be acquired, is much more frequently born with the individual, so that in the majority of the mentally afflicted we find a directly inherited predisposition to insanity."

Contrary to generally accepted medical opinion, as enunciated in the writings of alienists, the writer believes that the so-called exciting causes of insanity play a very unimportant part in the etiology of this disease, except in so far as they may operate to engender a state of brain denutrition and thus set in motion, hitherto latent inherited conditions or tendencies. The study and observation by the writer, during a period of thirty years, of thousands of cases of insanity with reference to causation, have served to convince him that only those who are predisposed to mental disease, either through inherited or accidental psychoneurosis—as head injury or organic disease of the brain cortex which renders the brain unstable—the latter being comparatively rare—succumb mentally to the influences which are embraced within the category of exciting causes. In support of this claim attention is called to the fact that substantially every individual at sometime during his life is exposed, in many cases

* Berkley.

repeatedly, to many of the so-called exciting causes of insanity, both mental and physical, and yet, despite this fact, we find that sanity is the rule,—insanity, the exception.

Let us take, for example, that best understood, most hopeless and most fatal of all forms of mental disease, paresis, which authorities are wont to attribute, at least in a vast majority of cases, to brain syphilis, excessive venery and other excesses of an exhausting nature, and how rarely we find a victim of this disease, whose history, on careful inquiry, fails to reveal the existence of an inherited psychopathic taint, either in the direct or collateral lines of descent. On the other hand, how few of those within the knowledge of every experienced practitioner who expose themselves recklessly to the conditions which are regarded as most potent in the production of paresis, ever become affected by that disease. Savage, who regards psychoneurotic predisposition as the chief predisposing cause of insanity, declares his belief that only a certain number of persons are so constituted that they can become insane.*

In taking the position that substantially all insanity is due either to inherited or acquired predisposition; that is, that it rarely occurs in individuals who are not predisposed thereto, either through hereditary or accidental psychoneurosis, the writer would by no means imply that every predisposed individual is likely to become insane, even though exposed to exciting causes. On the contrary, many of this class escape through the neutralizing effect of one parent, or through insufficient exposure to exciting causes or through intervention of the law of variation which renders the action of inheritance uncertain. Through the operation of this law the psychopathy of a father or mother may not appear in the descendants until the third generation is reached; or, out of three children hereditarily predisposed one, two or even all three may escape. If it were absolutely certain that every one, who is predisposed to insanity, would develop the disease under the influence of exciting causes, we should have less difficulty in making a satisfactory reply when consulted as to the advisability of such persons entering into marriage contracts, as it would then be our duty to forbid them absolutely.

In conclusion, hereditary predisposition may be regarded as an etiological factor common to all insanities, no matter what the immediate or exciting causes may be; that is, it may act independently as a causative factor or it may act in conjunction with what are denominated exciting causes.

Sarcoma of the Toes.—Léon Lefebvre reports the case of a carpenter, aged 17, who had a tumor of the second and third toes, painful, red, and somewhat elastic. The inguinal glands were swollen and hard. Both toes were amputated and the enlarged glands excised. Three months later tumors appeared at the situation of the anterior tibial gland, and in the iliac fossa. After five months they were excised. A month later the popliteal glands were found swollen. They were also extirpated. All the specimens were sarcomatous. The prognosis is serious, for the tumors will probably yet develop along the thoracic duct, or in the lungs, since it was impossible to extirpate the iliac glands thoroughly. ACUTE ALCOHOLIC MULTIPLE NEURITIS WITH PECULIAR CHANGES IN THE GASSERION GANGLIA.*

By CHARLES W. BURR, M. D.,

Neurologist to the Philadelphia Hospital.

and DANIEL J. MCCARTHY, M. D.,

Associate in the William Pepper Clinical Laboratory, University of Pennsylvania.

The case presented in this paper is interesting on account of the occurrence of palsy of the bladder and rectum, peculiar changes in the Gasserion ganglion, and the degeneration of the nerves going to the pelvic viscera. The patient's history is as follows:

Mrs. B. K., act. 37, was admitted to the Philadelphia Hospital on January 11, 1901. Her family and previous personal history was negative except that she had been a heavy drinker for years. The patient's history is as follows: One week before admission to the hospital she began to have pains and numbness in the extremities, muscular tenderness and weakness.

Examination. She was a fat, flabby woman with a flushed and bloated face. Her lips and teeth were covered with dried blood. She was dull and stupid. She was able to answer simple questions, but could not give any coherent account of her illness. The muscles of the legs were soft and there was great loss of power, but she was still able to flex and extend the feet, also the knees, to a slight extent, and to move the hips a little. Later there was almost complete loss of power in both legs with marked foot drop. There was complete extensor and quite marked flexor palsy of both forearms. The upper arm movements were also weak. At first she had control of both bladder and rectum, but about a week after admission both became paralyzed. There were no cranial nerve palsies. All the deep reflexes were absent. The nerve trunks and the muscles of the arms and legs were very sensitive to pressure. Tactile sensibility appeared to be normal, but hot and cold were often confused. She lost flesh rapidly not only from general emaciation, but also from local atrophy in the arms and legs. She was delirious or stupid the greater part of the time, but was mentally clear at intervals. A slight grade of jaundice developed toward the end. There was continuous slight fever averaging between 99° and 100° and twice rising to 102° for one night. The pulse rate ranged from 100 to 130; the respiratory varied from 26 to 40 per minute. For several weeks before death she had great difficulty in breathing without there being any physical signs to account for it. On February 13, 1901, her temperature fell to 97°, and she died, the radial pulse ceased to be felt some time before death.

The autopsy revealed cirrhosis of the liver; slight fatty degeneration of the kidneys and slight general arteriosclerosis. The other viscera, including the lungs were normal. Microscopic examination of the peripheral nerves by the osmic acid fresh method revealed parenchymatous degeneration of the vagus, median, ulnar, peroneal and phrenic nerves, the vesical and sacral plexuses and the corresponding anterior and posterior spinal roots. Staining confirmed the presence of this degeneration and also revealed in the vagus and phrenic hemorrhagic extravasations between the nerve bundles and within the sheaths. Examination by the Marchi and Weigert method showed that the degeneration became markedly lessened as the central ends of the nerves were approached. The intramuscular nerve filaments were extremely degenerated and the muscle fibers by the Marchi method showed local areas of degeneration. The rest of the muscle structure surrounding these areas was unaffected.

The central nervous system studied by the Nissl, Weigert and Marchi methods and treated with the nuclear and other stains showed marked alterations. Widespread and intense chromatolysis with at times vacuolization was present in the anterior horn cells, the cells of Clarke's columns and those of the bulbar nuclei. There was intense con-

*From the William Pepper Clinical Laboratory, Phoebe A. Hearst Foundation.

**Read before the American Neurological Ass'n, Boston, June 20, 1901.

gestion of the gray matter throughout the entire cord and medulla. The Marchi method showed intense acute degeneration of the posterior columns, the direct cerebellar tract, and to a lesser degree throughout the entire cord. The anterior and posterior roots, both intra and extra medullary, were markedly degenerated. The Weigert and carmine stains confirmed these changes and revealed an old and quite extensive perivascular sclerosis affecting the posterior and lateral tracts, (see fig. 1), presenting the appearance somewhat of a postero-lateral sclerosis (combined system disease).

FIG. 1.—Spinal Cord of Case 1, showing degeneration in the posterior and lateral tracts; also a very marked perivascular sclerosis stained by Weigert's method; the intense congestion of gray matter is well shown, as are also the lighter colored areas indicating the degenerative portion of the cord. The white streaks are areas of sclerosis surrounding small distended thickened capillaries.

The Gasserian ganglion was markedly altered. The nerve fibres were degenerated like the other peripheral nerve and nerve roots. The ganglion cells were in a condition of almost complete chromatolysis, vacuolated and very many of them completely destroyed and infiltrated with a calcareous material staining a deep purple with haemalum and presenting a peculiar semicrystalline structure. These areas were still surrounded by the cell capsule and presented a totally different picture to other areas of infiltration of a similar nature in the neighborhood of the smaller vessels. Such areas were small in size, and bunched in the form of rosettes about the vessels. At no time did they show the peculiar concentric arrangement of the concentric bodies found in the aged and in the *douloureux* (Spiller-Barker).¹ The vessels of the ganglion and elsewhere revealed evidence of an active pathological process in the thickening of the media and a marked increase of the number and size of the nuclei of the vessel walls. The most marked and striking changes were found in the cell capsules and in the interstitial tissue. There was a very marked round cell infiltration in the stroma of the ganglion without any special congestion of the ganglion. These cells were not leukocytes nor were they the small round cells found in inflammatory conditions, but were of larger size and more the shape and size of the connective tissue of the stroma. In the normal ganglion the ganglion cells are each surrounded by a capsule composed of a single layer of endothelial cells. In this ganglion the cells of the capsules had proliferated to such an extent as to form several layers about the cell and at times to completely fill the cell capsule, although this did not frequently occur, (see fig. 2). The only other condition in which these changes occur with any degree of constancy is hydrophobia. In the capsular changes of hydrophobia, however, the original layer of capsule cells is preserved, the proliferation occurring internally toward the centre of the cell, whereas in this specimen the proliferation occurs both internally and externally to the capsule with complete obliteration of the original layer of capsular cells. The

new formed cells are very different from those found in hydrophobia; here we find the cells with a distinct cell body and forming laminated layers of cells around the cell like so many connective cells. Such a condition of these cells is rare in hydrophobia, where we usually find but little tendency to form a spindle cell body and merely nuclei to indicate the cell proliferation. These changes together with the calcification of the ganglion cells has led us to the conclusion that these ganglion changes, especially the capsular changes are of a chronic or at least of a very subacute character with possibly an acute exacerbation towards the end of the disease.

FIG. 2.—Gasserian Ganglion of Case 1 (alcoholic multiple neuritis) showing interstitial and pericellular and intra-capsular small round cell infiltration.

A. Capsule entirely filled with proliferated cells.
B. Nerve cell almost completely degenerated; the nucleus has disappeared and the cell is shrunken.
C. Proliferated stroma cells.

To sum up we have a case of acute alcoholic multiple neuritis, with involvement of the bladder and rectum and acute widespread degeneration of the central and peripheral nervous systems, of the pelvic nerves, the vagus, and phrenic with hemorrhagic extravasation within the sheaths of the latter; degeneration of both fibre and cellular structure of the Gasserian ganglion (the other intervertebral and cerebral nerve ganglia not being examined) and intra and extra capsular round cell infiltration and proliferation about the ganglion cells which were in an advanced state of chromatolysis.

The changes in the Gasserian ganglia may be of some clinical and pathological significance and importance. Van Gehuchten and Nélis, in an article on rabies ascribed the paralysis to changes found in the intervertebral ganglia, which often were not as intense as the changes found in the ganglia here described. They came to this conclusion because no degeneration was found in the motor fibres from the cortex to the muscles and did not sufficiently take into consideration the cell changes of the spinal cord at times occurring in rabies. In any event it will be worth our while even with the presence of degeneration of the nerves sufficiently intense to cause the symptoms in alcoholic palsies, to bear in mind the possibility of these ganglionic changes as a contributory factor in the production of the spinal and cranial nerve palsies. The capsular lesions in the ganglia are in all probability due to

1. Spiller—*Jn. Am. Med. Ass'n*, 1900, P. 1094.
Barker—*Jn. Am. Med. Ass'n*, May 5, 1900, P. 1093.

2. Van Gehuchten and Nélis *Bull. de l'Acad. Royal de Med. de Belgique*, 4 Serie 14, 1900.

the irritant effect of the alcoholic or some metabolic poison, just as the lesions in rabies are due to an irritant product acting on these structures. Proliferation of the capsular cells has been described only two or three times outside of rabies³ in which it constantly occurs in advanced cases. In an article on this subject one of us in conjunction with Dr. Ravenel predicted, that such capsular changes would be found in diseases due to irritant toxins, but were unable to find them in an extensive investigation of tetanus and diphtheria. Crocq⁴ found in one case of fatal diphtheria, lesions analogous to rabies but differing both from that affection and the lesions described in this paper.

The bladder and rectal disturbances in alcoholic multiple neuritis are interesting, because it is usually taught, that they do not occur and that their presence is a differential point against multiple neuritis.⁵ Oppenheim states that, in the absence of delirium or unconsciousness, it should suggest some complications such as an involvement of the spinal cord." Pathological changes acute and chronic were present in this case. The acute changes, an extension of the peripheral changes to the spinal cord, are not infrequently found in a multiple neuritis unassociated with bladder or rectal symptoms. There was no palsy of the bladder and rectum until the development of the acute disease notwithstanding the chronic sclerosis. We are therefore of the opinion that, in the absence of any special lesions in the lumbar enlargement, the bladder and rectal incontinence was due to lesion of the peripheral neuron as manifested by the intense degeneration of the pelvic nerves and sacral roots.

From these findings it can be easily understood why impotence is met with in some cases and amenorrhea in others.⁶ It is also demonstrated in this case that a multiple neuritis with demonstrable lesions affecting the bladder and rectal nerves can occur, and too much stress should not be laid on this point in differential diagnosis from cord disease.

THE INFLUENCE OF SECONDARY INFECTIONS IN CHRONIC PULMONARY PHTHISIS:

An Introduction to a Discussion on Mixed Infection in Tuberculosis, July 26th, 1901.

By ALEXANDER G. R. FOULERTON, F. R. C. S.,

of London, England.

Bacteriologist to the Middlesex Hospital, Lecturer on Public Health and on Bacteriology to the Middlesex Hospital Medical School.

The influence which is exerted by secondary infections on the course and outcome of certain forms of tuberculosis in man is a matter of the greatest importance in the practice of medicine, and one which began to attract attention so soon as the identification of the specific parasite of the disease enabled its pathology to be studied with exactness. But the difficulty attending on the attempt to arrive at a true solution of this question is no less considerable than its importance; and it was with extreme diffidence that, at the request of the Secre-

tary of this Section, I undertook the responsibility of opening a discussion on mixed infections in tuberculosis.

Having once undertaken the responsibility, however, I felt that by dealing with the one aspect of the question which seemed to me to be of the greatest importance practically, I could better supply material for debate than by merely recapitulating generally the opposing views on this matter which have been put forward by different pathologists; views which are well known to all of you, and which will doubtless be revived and discussed by succeeding speakers.

My own remarks, then, will be limited almost entirely to the consideration of the part played by secondary infections in that form of tuberculosis in which the complication is most markedly manifest, and in which the results of secondary infection are, as it would seem, most disastrous, that is to say, in chronic pulmonary tuberculosis as it occurs in adults.

Chronic Pulmonary Tuberculosis and Chronic Pulmonary Phthisis.

Whilst there can be no question as to the cardinal part which *bacillus tuberculosis* plays as the primary, or original, factor in the condition known as chronic pulmonary phthisis, the influence of the specific parasite in the production of the symptoms characteristic of this condition, and its importance as an ultimate factor in the excessive mortality caused by the disease, are not by any means so well established.

Frequently, indeed almost invariably, the terms chronic pulmonary tuberculosis and chronic pulmonary phthisis are used in clinical medicine as if synonymous; whereas pathologically the two conditions differ widely, although agreeing in the fact that *bacillus tuberculosis* is present in the lesions of each. In uncomplicated chronic pulmonary tuberculosis the single organism present, the specific bacillus, is one which, under the given conditions, does not manifest more than a quite low degree of virulence in the majority of cases, whether as regards its direct action on the tissues actually infected, or as regards its action on the system as a whole by the production of toxins. In chronic pulmonary phthisis, on the other hand, to the action of this parasite is added the more acute influence of pyogenic organisms, whose potentiality for evil, again under the given conditions, is incomparably greater, whether by direct action on the tissues infected, or by the production of toxins.

That success in treatment is founded on the correct pathology of a disease is the most obvious of truisms; and since a further reduction of the still excessive mortality from pulmonary phthisis is one of the two great objects to which the efforts of public medicine of the present day are most earnestly directed, the importance of a true appreciation of the influence of the several factors which cause this mortality can scarcely be overstated. In dealing with chronic pulmonary phthisis, are preventive and curative measures to be directed exclusively against the specific parasite of tuberculosis, or are we to regard the secondarily infecting organisms

6. Buzzard quoted by Oppenheim Lehrbuch.

* From advance sheets furnished by our representative at the Congress on Tuberculosis, London.

as factors of equal, or even greater, importance in the causation of the mortality?

And in seeking an answer to this question, the first thing that one has to consider is, what is the nature of chronic pulmonary tuberculosis before the occurrence of secondary infection has converted the condition into one of chronic pulmonary phthisis.

Uncomplicated Chronic Pulmonary Tuberculosis.

By uncomplicated chronic pulmonary tuberculosis I understand is meant the condition in the lungs brought about, usually in adults, by the presence of *bacillus tuberculosis* alone, in which a limited number of granulomata in various stages of development and degeneration are present in the tissues infected, and in which infection has in a very large majority of cases occurred by way of the air passages.

The fact that such a condition usually results from direct air-infection is rendered probable by what one observes in the experimental infection of animals.

In lower animals the conditions which correspond with general miliary tuberculosis and with chronic pulmonary tuberculosis can be produced at will according to the method of inoculation practiced. If one causes a general blood infection by the injection of *bacillus tuberculosis* directly into a vein, the result is manifest in the development of a large number of gray miliary tubercles in the lungs—the common seat of arrest and lodgment of bacteria circulating in the blood—in the spleen, and elsewhere. The animal usually dies from the effects of the infection before sufficient time has elapsed for the granulomata to undergo the degenerative changes found in cases of tuberculosis in which the degree of primary infection has been less intense.

If, on the other hand, the animal is made to inhale infected dust, one gets a chronic, and at first strictly localized, tuberculosis, such as is the first stage towards chronic pulmonary phthisis. Under these conditions, unless the initial dose of bacteria inhaled has been excessive, life is sufficiently prolonged for the resulting granulomata to undergo the successive degenerative phases seen in the lesions of chronic pulmonary tuberculosis in man.

The first thing to be noted about uncomplicated chronic pulmonary tuberculosis in man is that the condition is comparatively rarely met with by the physician in his practice, and that the opportunity for the study of its morbid anatomy is found mainly in patients who have died from some other disease. It is rarely recognised by the physician, because of the absence of any definite symptoms produced by it in the majority of instances, such cases as are diagnosed being usually those in which a certain amount of cough has attracted attention to the chest, and the sputum has in consequence been examined. In such cases physical signs and definite symptoms of disease are most frequently absent; and the discovery of the infection by the finding of bacilli in the sputum is usually almost a matter of accident.

On the other hand, such a condition of uncomplicated chronic pulmonary tuberculosis as being the initial stage of chronic pulmonary phthisis must, we know, be an extremely common one; and the frequency of its occurrence is emphasized when we

consider, not only the number of cases in which secondary infections have determined the onset of definite pulmonary phthisis, but also the large number of cases of pulmonary tuberculosis which there is reason to believe never arrive at that stage, and are not recognized at any time during life. The frequency of these latter cases can only be estimated from the number of instances in which lesions, usually of limited extent indicative of cured or arrested tubercular infection, are found in the lungs of adults dying from other causes.

Ample evidence of this has been brought forward by many pathologists, and I need now only quote the following facts.

The condition of the lungs with regard to evidence of past disease has been recorded with particular care in the case of all patients dying with malignant disease in the cancer wards of the Middlesex Hospital, during the eighteen months. In all 128 such cases have been examined during the period, and the following results have been tabulated.

Age.	Lungs free from any lesions suggestive of recent or cured tuberculosis.	Lungs with lesions suggestive of recent or cured tuberculosis.
1—20	3	—
21—30	2	—
31—40	6	3
41 and over . .	80	34

The lesions found may be roughly classified as follows:—

Recent localized tuberculosis, 3 cases,

Caseous or calcareous nodules in lungs, 18 cases.

Cicatrization of lung substance, 16 cases.

In all these cases the extent of the lesions was limited; and in not one case was any actual history of past phthisis obtained during life. Of the cases in which lung lesions of one sort or another were found, there was absolutely no history of any chest trouble at all in thirty-four; in the case of the remaining three the following histories were given. One patient had suffered from "inflammation of the lungs," and another from "chronic bronchitis," both some years previously, whilst the third, a woman aged 34, stated that she had suffered from "spitting of blood" seventeen years previously. Seven of the ninety-one-patients who, after death, showed no lesions in the lungs had also given a history of either "bronchitis" or "inflammation of the lungs" at some time previous to admission.

Excluding the three cases of recent tubercular infection, the result of the investigation shows that of one hundred and twenty patients of both sexes who had survived beyond the age of thirty, thirty-four showed definite evidence of past destruction of lung substance, with subsequent arrest of the disease which caused it. And knowing from *post-mortem* examinations the relative frequency of occurrence of diseases which cause such destruction of lung substance, it cannot be questioned but that a large proportion of these thirty-four patients had at one time or another suffered from pulmonary tuberculosis.

Dr. Lazarus-Barlow has been kind enough to give me the results of the last one hundred and sixty-two consecutive *post-mortem* examinations which he has carried out at the Westminster Hospital on

adults over the age of thirty dying from diseases other than tuberculosis. Of one hundred males, eighteen showed evidence of arrested tuberculosis; and of sixty-two females, fourteen showed similar evidence. This gives a proportion of thirty-two cases of arrested tuberculosis in one hundred and sixty-two of both sexes. We find, then, that in individuals dying from causes other than tuberculosis a considerable percentage show evidence of having at one time or another suffered from a localized pulmonary tuberculosis which has not been sufficiently severe to attract notice during life by definite symptoms. If we compare the ratio of deaths from chronic pulmonary phthisis to deaths from all other causes, other than the various forms of tuberculosis, in adults over the age of thirty, we can gain some idea as to the frequency with which the arrest and cure of chronic pulmonary tuberculosis occurs without a development into pulmonary phthisis.

We next have to consider the nature of the bacteria which by infecting the lesions of chronic pulmonary tuberculosis convert that condition into one of chronic pulmonary phthisis.

The Secondarily Infecting Bacteria of Chronic Pulmonary Phthisis.

Our knowledge of the flora of pulmonary tubercular cavities has been arrived at by the examination of (1) the sputum discharge during life, and (2) of the walls and contents of the cavities after death.

Examination of the sputum has usually been carried out after the plan suggested by Kitasato; the mouth is well rinsed out, the sputum caught in a sterilised vessel, and washed repeatedly with sterilised distilled water. Culture media are then inoculated with the sputum and incubated.

Using this method, the error arising from contamination by bacteria from the mouth and pharynx is reduced as much as possible, and on comparing the results of the cultures with stained specimens of the sputum a reasonably accurate estimate of the relative proportion in which any bacteria are present in the pulmonary lesions during the progress of the disease may be obtained. Cultivation of the bacteria found in the contents of the cavities after death, and microscopic examination of the cavity walls, appear to me as a method of examination of rather less value than the preceding; the results obtained are, so far as the particular object in view is concerned, very liable to be vitiated by the occurrence of bacteria which have infected the cavities only during the last few hours before death, or afterwards, and which consequently have had no influence on the progression of the disease during life. A full catalogue of the literature embodying the work of those who have dealt specially with the species of bacteria which infect such cavities has lately been published in Sata's monograph on Mixed Infections in Pulmonary Phthisis (I), and there is no need for me now to do more than mention the different species commonly found.

Practically all who have worked at the subject are agreed that various species of cocci are the predominating organisms in the secondary infection of tubercular cavities, *Streptococcus pyogenes*, *Staphylococcus pyogenes aureus*, *Staphylococcus pyogenes albus*,

Diplococcus pneumoniae, and *Micrococcus tetragenus*, being found more especially. Amongst other bacteria of less common occurrence under these conditions are, *Bacillus coli communis*, *B. pneumoniae*, of Friedländer, *B. pyocyaneus*, species of *Protus*, and *Saccharomyces albicans*. Sata also describes *B. pseudodiphtheriticus* and *B. pseudodiphtheriticus pulmonalis* as occurring with some frequency.

Artault (2), again, has compiled a very full list of the bacteria which are found in cavities after death, but many of the organisms mentioned by him, and by others who have carried out this method of examination after death, must have been present as merely casual contaminations, and cannot be considered seriously as having had any definite influence on the course of the disease.

It is to the pyogenic cocci, and above the rest to *Streptococcus pyogenes*, that we have therefore to look when considering the effects of secondary infections as exercised through the lengthened course of a case of chronic pulmonary phthisis.

The Pathogenic Action of the Secondarily Infecting Bacteria.

It may next be asked in what manner it is that these cocci exert an injurious influence; a point which must be dealt with in some detail. And the action of such organisms may be considered, first as to their action locally on the tissues actually infected, and secondly, as to their effects on the system generally.

The local effects are manifest by an active destruction of the tissues actually infected, by the occurrence of perinodular pneumonia, and by what may be described in general terms as a lowering of the powers of resistance—a lowering of the vitality of tissues in the neighborhood of those actually infected; the latter effect being partly due to the direct action of toxins produced by the bacteria, and partly to vascular disturbance in the proximity of the lesions.

There action on the system at large may be expressed either by the results following on the absorption of toxins, toxemia, or by those of an actual infection of the blood generally by the bacteria themselves.

From these ways in which the secondarily infecting bacteria might act injuriously, we may, I think, exclude a general blood infection as being a factor of any importance in the pathology of chronic pulmonary phthisis, save only as a terminal infection.

Evidence on this point is afforded the examination of the blood during life, and of the blood and organs after death.

Petruschky (3) examined the bodies of fourteen patients who had died with pulmonary phthisis, and in eight cases isolated streptococci from the blood and internal organs. These observations are of value only as establishing the relative frequency in phthisis of terminal infection by the organism which is the predominant secondarily infecting parasite during life, and beyond that have no direct bearing on the pathology of the progressing disease.

Jokowski (4) examined blood, drawn from the finger, from patients in the hectic stage; in eight

cases out of nine thus examined. Jakowski obtained cultures, either pure or mixed, of *Staphylococcus pyogenes aureus*, *Staphylococcus pyogenes albus*, *Streptococcus pyogenes*. The method of examination used has, however, now become obsolete because of the difficulty of avoiding contamination, and in the light of recent work Jakowski's results must be looked upon with suspicion. Thus Straus (5) on making cultures from the blood of phthisical patients, "en pleine fièvre hétique," the blood being obtained with a syringe directly from a vein, found it absolutely sterile in every case out of thirteen examined.

Mangin-Bocquet (6) similarly examined the blood from seven cases of advanced phthisis, one cubic centimetre of blood being withdrawn from a vein and transferred to culture media. In five out of the seven cases the culture tubes remained sterile; in the other two cases a small proportion of the tubes inoculated showed a growth of a white coccus.

The balance of evidence afforded by these and other observations allow us, then, to exclude general blood infection as a factor of any consequence in the present discussion. And the effect of secondarily infecting organisms has to be considered only with regard to their local action and with regard to the production of a toxemia.

Method of Secondary Infection.

The method by which secondary infection occurs may just be mentioned. In normal tranquil respiration, carried on through the nostrils, all bacteria in the air inspired are arrested in the anterior part of the nasal passages, and so the air which passes through the glottis into the lungs is under ordinary circumstances free from organisms.

This arrangement is necessarily disturbed by the act of coughing, when a sudden and deep inspiration through the mouth occur preparatory to violent expiratory efforts. And under these circumstances potentially pathogenic bacteria will pass with the rush of air through the glottis, and into the lungs, the working of the normal mechanism for their arrest being in abeyance.

Assuming that the lining cells of the lower portion of the respiratory tract are in a healthy condition, and that the dose of inspired bacteria is not excessive, the natural germicidal power of the healthy mucous secretion will probably be sufficient to destroy the activity of any invading bacteria before mischief is done. If, however, portions of the mucous lining have their vitality impaired by the irritation caused by neighboring tubercular nodules, or if granulomata have, in breaking down, exposed small cavities containing caseous material, any invading bacteria find conditions favorable for their growth, and are able to effect a lodgment.

It is of some interest to note that the bacteria which are under normal conditions arrested in the fore part of the nasal passages are amongst those which are most frequently found infecting pulmonary cavities. Thus von Besser (7) on examining the nasal secretion of fifty-seven individuals found *Diplococcus pneumoniae* present fourteen times, *Staphylococcus pyogenes aureus* fourteen times, *Strepto-*

coccus pyogenes seven times, and *B. pneumoniae* (Friedländer) twice.

Apart from the infection of the lungs by inspired air, one must just mention secondary infection down the trachea by direct continuity of surface, in cases where there is a laryngitis, as a possible mode of secondary infection of tuberculous lesions in the lungs.

Comparison of the Pathogenic action of *B. Tuberculosis* and the Secondarily Infecting Bacteria in the Production of the Characteristic Phenomena of Chronic Pulmonary Phthisis.

Uncomplicated chronic pulmonary tuberculosis being a condition which, in a large majority of the cases in which it occurs, does not of itself give rise to serious symptoms, and which, in a probably considerable number of the cases in adults, appears to become spontaneously arrested, we have next to consider to what extent the serious and fatal features of chronic pulmonary phthisis are due to the further growth of *B. tuberculosis* and to the secondarily infecting bacteria respectively.

Taking the primary pathological features of fully developed chronic pulmonary phthisis during life as including (1) evidence of active destruction of lung tissue, and (2) the production of what is termed " hectic fever," with its accompanying high evening temperature, morbid sweating, and wasting of the tissues generally, we must at the start allow that infection of a cavity by, for instance, *Streptococcus pyogenes* will afford a satisfactory explanation of all the phenomena. On the other hand, we find good reason for believing that *B. tuberculosis* by itself would not—at any rate, under the conditions which prevail in what may be termed a "chronic infection," such as we are now considering—be capable of producing these effects in anything like the extent to which they occur. As to active destruction of tissues, this is never a direct effect of a pure infection by *B. tuberculosis*. A slow destruction of tissue does, of course, occur, but only because of the breaking down of granulomata, the very presence of which, as they occur in tuberculosis, is evidence of a low grade of virulence in the parasite producing them. The organism comes to rest at some point in the tissues, and its presence there is just sufficient to determine an aggregation of round cells, from which the granuloma is developed. A quite similar result may be produced by a purely mechanical irritation, and up to the time when the granuloma is fully developed, there is, so far, no evidence whatever of any active destruction of tissues. The subsequent degenerative changes which the tuberculous granuloma may undergo are to be attributed quite as much to a cutting off of the blood supply of the cells concerned as to any injurious action on the cells by the bacteria contained in the lesion; and with these changes there is no active destruction of the living tissue neighboring on the caseating or breaking-down granuloma, but merely a certain amount of round-cell infiltration, which, in the neighborhood of the simple tuberculous granuloma, is always of slight extent.

With regard to the secretion of toxins, which by a toxemia might produce general or constitutional symptoms, all that one can say is that in all forms

of chronic pure tuberculosis in parts other than the lungs, the symptoms which can be attributed to such a toxemia are either of the slightest, or conspicuously absent. When one does get symptoms due to an acute infection by *B. tuberculosis* they are of a quite different character, not merely in degree but in type, from those of chronic pulmonary phthisis. The comparative inertness of chronic tuberculosis disease, before an entirely new feature has been added by secondary infection, cannot be better illustrated than by what occurs in cattle. An ox may have the most tuberculous infection of the pleural or peritoneal sacs, and yet will frequently be in absolutely prime condition, there is no suggestion of disease until the tuberculin test is applied, or the animal is slaughtered. But given a breaking down of tubercles in the lung substance, with secondary infection of the cavities, or an ulceration of tuberculous lesions in the intestine, and one finds the same high temperature, the general wasting, and the same active destruction of the infected tissue which characterize the average case of chronic pulmonary phthisis in man. In cattle the effects of tuberculosis depend not on the extent of the specific lesions—so long at least as these are localized—but rather upon the occurrence of secondary infection. When one considers more especially those forms of chronic infection which come more commonly under the care of the surgeon, one finds the same thing; so long as secondary infection by pyogenic bacteria is absent, constitutional symptoms indicative of any serious toxemia are wanting. When a secondary infection occurs, either spontaneously or as the result of operative interference, one gets the same train of general symptoms as those which mark the transition of uncomplicated pulmonary tuberculosis into chronic pulmonary phthisis.

I may, perhaps in the short time which remains, quote very briefly two cases which I have recently been able to follow closely, and which illustrate my contention as to the change brought about in chronic tuberculous disease by the supervention of secondary infection.

The two cases were at first apparently ones of uncomplicated chronic pulmonary tuberculosis in men, aged thirty-four and about twenty-four respectively. Neither complained of any definite symptoms, except cough; in neither was the temperature, when the cases first came under notice, above 99° F. in the evening. The older man was powerfully built, and well nourished; the younger man was of slight build, but not of unhealthy appearance. Both had been examined by skilled physicians, and in both I was told that definite physical signs of chest disease were absent, except that in the older patient there were some indications of old pleural inflammation, and in the younger patient a very indefinite suggestion of some impairment of resonance at the right apex. In both the disease ran very much the same course. When the sputum was first examined it consisted of a tenacious mucoid mass, a small quantity of which was discharged on rising in the morning. This contained in each case an abundance of *B. tuberculosis*, and no other bacteria except a small quantity of cocci from time to time, these

latter, when isolated, appeared to correspond with *Staphylococcus pyogenes albus*, and were not present on every occasion when the sputum was examined. After a few months in each case—during all which time periodical examinations of the sputum were being made—chronic pulmonary phthisis became well established. And in each with the development of physical signs in the chest, and wasting, night sweats, and high evening temperature, large quantities of *Streptococcus pyogenes* appeared in the sputum, with marked alteration in the physical characters of the expectoration and in its quantity. And no one who had examined the sputum, and watched the change in the patients, could have doubted the relation of the appearance of the pyogenic organism to the progress of the case.

Believing, then, that secondary infection of the lungs is the chief, or at any rate the immediate, cause of the excessive mortality from pulmonary phthisis, it is permissible to ask whether the pathology of these infections can throw any light upon their treatment.

The Treatment of Secondary Infections in Pulmonary Phthisis.

Stated generally, I believe that the teaching of pathology on the matter is that the treatment of secondary infections should be the chief object aimed at in the first place.

Believing strongly as I do that ultimate success in the specific treatment of declared tuberculosis will be attained with some modification of tuberculin, I also feel that the comparative failure of the method in the past, and the consequent discredit which has fallen on it, have been almost entirely due to the ignoring of the effects of the common secondary infection of the lung lesions by pyogenic cocci. Knowing as one does the intense reaction in the neighborhood of tubercular lesions which may follow the use of tuberculin, it is difficult to understand how its use in a patient whose lesions are secondarily infected and lung tissue damaged by actively virulent pyogenic bacteria could fail to be followed by disastrous consequences. Before any attempt at the use of such a method should be made, the extent of any secondary infection should be carefully taken into consideration. And, whilst a very large proportion of the cases which come under treatment will have already suffered this secondary infection, the question must arise as to whether any practical steps can be taken to reduce the intensity of such an infection by pyogenic cocci. And I think that one can fairly claim that in cases of average severity efficient steps might be taken in this direction. By keeping a patient who has a cavity infected by pyogenic cocci in an atmosphere of practically germ-free air, such as may be found at moderate altitudes, and by enforcing the nearest approach to complete physical rest possible, one can not merely protect him against the risk of reinfection by pus organisms, but also one places him under conditions in which the work that has to be done by a damaged lung is reduced to a minimum. With the patient thus protected as far as possible against any reinfection of the cavity, one may confidently hope that the intensity of the present pyogenic in-

fection will be reduced. It is a matter of common experience that when pyogenic bacteria are confined in a limited space, and are kept from reinforcement from outside, that their virulence becomes attenuated, and that after a time they tend to die out. Thus the streptococcus from an old empyema, old pyosalpinx, or chronic abscess of any sort will often be found to have lost much, or all, of the virulence which it originally must have possessed. Charrin and Guillemonat (8) have recently shown that the same attenuation of virulence in intestinal bacteria takes place when an animal, without any special preparation, is kept in an atmosphere of sterile air and fed on sterilized food. In the absence of reinforcement from without, the number of intestinal bacteria is markedly diminished, and the vitality of such as survive is distinctly lowered. If, therefore, a patient is kept under the conditions which I have spoken of, one may expect that improvement, so far as the pyogenic infection of cavities is concerned, will follow. And it is probable that this is what happens in most of the cases in which apparent arrest of phthisis follows treatment in well ventilated hospitals and sanatoria. Every one knows, however, the common after-history of such cases. A working man as the result of such treatment puts on weight, night-sweats disappear, the physical signs become insignificant, and as I said, the tuberculosis is looked upon as being arrested, or even cured. What has probably really happened is that, with the disappearance of secondary infecting bacteria, the pulmonary phthisis has reverted to the former condition of uncomplicated pulmonary tuberculosis. If the patient returns to his old surroundings, a reinfection with pyogenic cocci from the foul air in which he lives occurs, and the case slowly drifts back into one of chronic phthisis again. Or if the conditions are more favorable, the proper tuberculous lesions may in time undergo a natural cure in the absence of any re-infection.

The constancy with which a recrudescence of the disease happens in patients with arrested phthisis discharged from sanatoria and hospitals to their old surroundings cannot be attributed to re-infection with *B. tuberculosis*, and no other explanation than a re-infection of tuberculous lesions with pyogenic organisms will suffice.

I have laid some stress upon this matter, because it is just in this stage of arrested phthisis, that specific treatment of the now more or less pure tuberculosis with tuberculin should have the most chance of success. The lungs being free from pyogenic organisms the result of the specific reaction might be expected to be far less severely felt, and a real cure of the tuberculosis might be hoped for.

In addition to the treatment by rest and pure air, it is likely enough that a systematic treatment with anti-streptococcal serum in cases in which *Streptococcus pyogenes* is the predominating organism, and those cases form a large proportion of the whole, would help materially in shortening the time which must elapse before any specific treatment for the tuberculosis can be safely attempted.

Other problems of interest in connection with

the subject of mixed infection in pulmonary tuberculosis, which I have not had time to touch on, are (1) the effect of secondarily infecting organisms on the progress of the tubercular infection itself, a question on which diverging views have been expressed, some holding that the growth of the bacillus is thereby checked, and others that its dissemination is favored; and (2) the exact pathology of those cases in which phthisis rapidly supervenes after some infective diseases, such as typhoid fever, influenza, or variola. Are such cases the result of secondary infection of a lung already the seat of latent tuberculosis, or are they the result of a secondary infection by *B. tuberculosis* of a lung already damaged by bronchitis or pneumonia in the preceding specific disease?

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended October 19, 1901:

The Fourth Disease.—It is perplexing, after examining a child suffering from an exanthematous disease, to make a diagnosis of measles and then to be told that the patient has had the measles before; it is even possible that two former attacks of measles may be claimed for the patient. It has long been taught that one attack of an infectious disease protects the individual against a second attack; and researches in bacteriology, followed, as a natural consequence, by studies on immunity, have shown that the microorganisms of these diseases require a virgin soil for their growth and that their biological processes produce such changes in the body of the host that the soil is exhausted for the development of that particular germ. Long ago measles and scarlet fever were thought to be one disease, until, in the seventeenth century, Sydenham clearly demonstrated the differences between them. Later, the term measles was shown to include two diseases, the second of which was termed rubella, rōtheln or German measles. In this country, Smith, Holmes and Griffith, among others, have been instrumental in giving rubella its place as a distinct disease. Many writers describe a form of rubella that resembles measles in its symptomatology, *rubella morbillosa*, and a form that resembles scarlet fever, *rubella scarlatinosa*. It is the latter group of cases that leads to grave anxiety on the part of the physician. If the disease is scarlet fever, a period of isolation of from forty-two to fifty-six days is required before it is safe to allow the patient to resume his customary habits. If the disease is rubella, a shorter period of isolation is required. Clement Dukes (*Lancet*, July 14, 1900, p. 89) is convinced that there are two diseases included under the term rubella, rose rash or German measles; the one, rubella; the other he names "the fourth disease." This disease presents no premonitory symptoms, vomiting is usually absent, and the eruption, which is like that of scarlet fever, is the first symptom to attract attention. The fauces are red and swollen, but they give rise to no discomfort, however severe the rash may be. In some instances the skin is merely rough, but in the majority of cases there is free desquamation of small scales; in still other cases the desquamation

is equal to the worst ever seen in scarlet fever. The tongue is furred throughout and there is no peeling of that organ on the fourth day as there is in scarlet fever. The lymph-nodes are universally enlarged, tender and hard. The temperature averages 101° F.; the pulse is usually below 100; albuminuria is never found. The incubation period probably varies from nine to twenty-one days. The continuation of desquamation, however, is of no consequence as a cause of infection or of sequelæ. The enumeration of the characteristics of the disease shows the main differences between it and scarlet fever. Furthermore, the disease is not a mild form of scarlet fever because both diseases occurred concurrently in the same epidemic, and some patients had both diseases in the same epidemic. The difficulties of distinguishing "fourth disease" from rubella are (1) the similarity of the symptoms in both, with the exception of the dual appearance of the rash. (2) The fact that in rubella the rash is at first discrete, like that of measles, but terminates by coalescing and assuming an appearance like that of scarlet fever. (3) Rubella and "fourth disease" frequently occur in the same locality at the same time. (4) The period of incubation is almost identical in both diseases. An attack of rubella, however, does not protect against "fourth disease." Simpson (*Archives of Pediatrics*, September, 1901) refers to an epidemic of an exanthematous disease in which there was difficulty in diagnosis. At first, the cases were thought to be cases of rubella; but later, were believed to be mild cases of scarlet fever. When, however, an attendant, who had previously had scarlet fever, contracted the disease, this diagnosis became doubtful. Many of the patients presented desquamation similar to that seen after an attack of scarlet fever. The incubation period was at least two weeks. Without positively committing himself, the author seems to incline to the opinion that this was an epidemic of "fourth disease." Ashby (*British Medical Journal*, September 7, 1901) in a discussion in the Section of Diseases of Children of the British Medical Association places himself in agreement with Dukes. He believes that there are two diseases included under the term rubella; the usual one with a

long period of incubation, German measles; and a rare one, only diagnosable when it occurs in epidemics.

The Health of the Army.—According to the forthcoming report of the Surgeon-General, the health of the United States Army for 1900 must be regarded as having been unusually good. Just before the Spanish-American War the admission rate (by which is meant the number of admissions to sick report) had fallen in 1896 to 830.65 per thousand, while the lowest death-rate (in 1897) was only 5.11 per thousand. The Spanish-American War of course sadly interfered with the continuance of this good record, but in 1900 the health of the troops began again to be something like normal.

The admission rate for all causes in the army, both volunteer and regular, with a mean strength of 100,389, in 1900 was 2311.81 per thousand. The troops serving in the United States (mean strength 20,690) had an admission rate of 1510.97 per thousand. The death-rate was 7.78 per thousand—4.83 from disease, and 2.95 from injury.

In the Philippines, with a mean strength of 66,882, the admission rate was 2621.96—an increase over the preceding year, due largely to sickness among newly arrived volunteers. Malarial and diarrheal diseases caused two-thirds of the admissions. The death-rate was 28.75 per thousand—20.26 being due to disease. This was a diminution. The health of the troops in the Philippines has been steadily improving. The Chief Surgeon reports that the rate of non-efficiency for the first six months of the present year was less than 7 per cent. The chief diseases were those already mentioned. Typhoid fever has not cut a great figure, and smallpox has almost disappeared. Only one case of plague occurred in the army, and that was in an enlisted Chinese cook.

The health of the troops in Cuba was excellent. With a mean strength of 8690, the admission rate was 1873.07 and the death-rate was only 9.78, as against 18.30 in 1899. Yellow fever was responsible for even a part of this not excessive death-rate, but as the report points out, the cities of Cuba are now well inspected and the death-rate should still further decline.

In China the death-rate was high—47.76. Porto Rico seems to be an ideal place for troops, and the records are about as good as for home stations. The admission rate was only 1577.98, as compared with 2522.40 for the previous year. The death-rate was only 5.05, as against 11.27 in 1899. This death-rate was lower than the lowest recorded death rate in the United States Army—5.11 per thousand in 1897.

Altogether the report of the health of the army, considering that a large part of the troops is serving in foreign and tropical lands, is not discouraging.

The American Troops in China.—The latest issue of the *China Medical Missionary Journal* contains an interesting paper by Dr. Charles Lewis, Surgeon to the U. S. Legation Guard at Peking, on the health of the American troops under his care during the recent campaign in China. He thinks, with reason, that American readers will be interested to know how these soldiers fared when they went to the relief of the besieged legation, and how many of them laid down their lives in the struggle. As Dr. Lewis was practically an eye-witness of most of the things he describes, his report has an especial value. His statistics refer to the army only, the men in the naval and marine service not being included.

Two battalions of the 9th Infantry were the first of these American troops to engage in active hostilities. In the battle of Tientsin they sustained a loss of 19 killed, including Colonel Liscum, and 66 wounded. These wounded were transferred to the hospital ship *Solace*. The 9th and 14th Infantry, and 5th Artillery, Battery "F," were in the battle at Yang-Tswen, and lost 7 killed and 59 wounded. At one place on the march to Peking, 96 men were overcome with the heat.

The above-named force, with the addition of a troop of the 6th Cavalry, took part in the engagement before the walls of Peking, where they suffered a loss of 6 killed and 31 wounded. After the capture of the city the American troops went into winter quarters in the Temple of Agriculture, and most of them remained there during the winter. The largest number present was in October, when the strength of the command was 4044. The average in this command for nine months of non-effective men was only 5.8 per cent.—a remarkably good showing.

The prevailing diseases during these nine months were diarrhea, dysentery, malaria, typhoid fever and venereal affections. Dysentery ranked first in its number of victims, but Dr. Lewis thinks that very much of this dysentery was imported from the Philippines by the troops coming from Manila; these soldiers were much debilitated on their arrival in China, and had the disease when they came. At autopsy the cases of dysentery showed extensive and deep ulceration of the colon, but no ulceration above the ileo-cecal valve. In most of the cases the whole surface of the large intestine was a succession of ulcers. But two deaths occurred from typhoid fever—both from perforation. A grave

form of pneumonia also developed and resulted in 12 deaths. Dr. Lewis says that this disease would have headed the list, had dysentery not been imported from Manila. He also calls attention to the fact that the health of the command during these nine months was better than in most posts at home—an exceedingly interesting fact, considering the circumstances, and one that goes to prove that North China is a healthful region. In spite of the fact that the men wore only felt hats, instead of the tropical helmet, there were no permanent injuries from heat. It is interesting to note, too, that the malaria encountered seemed to have been imported from Cuba or the Philippines, and the men who had it recovered after they had been in China for some time. Syphilis was the most common of the venereal diseases. The report is entertaining both historically and from the standpoint of military hygiene.

Tax-Rate and Death-Rate.—The city of Glasgow is reputed to be one of the best governed municipalities in the world. Its Municipal Council conducts the city's business on business principles, and the citizens, to whom the whole municipal plant belongs, obtain the benefits. A correspondent of *The Outlook* gives some of the figures on which the scheme is carried out. A small house of three rooms and a kitchen rents at \$160 a year, and the tenant (who in Glasgow has to pay the city taxes direct) is taxed \$24 a year. This tax would represent an assessed valuation on the real estate of about \$1300, according to the Philadelphia tax-rate. Of the \$24 thus paid, \$18 is made up of municipal charges, and the balance consists of a charge of \$3 as a poor tax, and \$3 as a school tax—the former rather high and the latter rather low, according to American ideas. There is an extra tax of \$3 for water. But real estate which is assessed at only \$1300 would hardly rent for \$160 a year (the tenant paying the taxes), so the inference is that the property is worth more than that sum, and that the tax-rate in Glasgow is not so high as in Philadelphia. In Glasgow, we are told, the people have great civic pride and regard the city itself as only a larger home than the house. They have half-penny fares on the street cars, fine schools, parks and art galleries, and a splendid and never failing water supply. But better than all, they have reduced the death-rate to fourteen per thousand, although the city has a bad climate and is a great industrial centre, and its death-rate was once notoriously high. From all this it would seem that the citizens of Glasgow have learned how to run their town on business and sanitary principles.

The Value of the Blood Examination in Surgical Diagnosis.—Two interesting and valuable contributions on the subject of the blood state in surgical diagnosis have appeared recently. (*The Annals of Surgery*, September 1901). The first of these represents a comprehensive study of the blood changes induced by ether, from the pen of John C. Da Costa and Frederick J. Kalteyer. They have studied the blood before anesthesia and after anesthesia in 50 cases, as well as having performed experiments on rabbits, in which they have found very marked changes suggestive of erythroblastic proliferation as a result of the ether, and they inquired in the light of this experiment whether the pains in the limbs and back, so common after anesthetization, are not due, at least in part, to changes in the marrow. In this experiment only a trivial amount of blood was lost. The conclusions of Da Costa and Kalteyer, bearing as they do the stamp of most careful study and conscientious work with a large amount of clinical material, are especially interesting in the light of the value of blood examinations to the surgeon. Briefly, they state that accompanying anesthesia there is usually polycythemia caused by a lessening of the watery elements of the plasma, and consequently causing concentration of the blood. The blood inspissation is, as a rule, most pronounced immediately after the termination of the anesthetic stage. The relative increase in the number of erythrocytes is generally still present some time after the operation. But not infrequently the adjustment of the watery and solid elements presents itself before this time and an oligocythemia may be present. The corpuscular hemoglobin value (color index) is always reduced after the termination of the anesthetic state. They were not able to determine the influence of the amount of ether nor the duration of the anesthetic state upon the blood, on account of the many modifying factors. They make the interesting observation that the blood loss does not seem to affect the state of the blood. On account of the hemolysis, which is shown by the fall in corpuscular hemoglobin index after operation, they believe that a general contraindication to operation is present if the hemoglobin is below 50%, and they state that if the hemoglobin is below 40%, a general anesthetic should not be given except under stress of absolute necessity, and when it is given, oxygen should be combined with it, and the operation should be performed rapidly. Proper methods should be taken to bring about reaction after its completion and oxygen inhalation should be used to remove the ether quickly from the lungs. The increasing importance of having some one administer the ether who is skilled and experienced in the work is also fully emphasized by these writers.

The second article to which we refer is that of

Cabot, Blake and Hubbard who have studied the effects of ether upon the leukocyte count; the effects of operation upon the leukocyte count and the effects of fractures upon the leukocyte count, as well as the regeneration of the blood after operations for malignant disease. They also have investigated 50 cases, and their findings are as valuable as they are interesting. They state that at the end of complete anesthesia, there is occasionally a slight increase of leukocytes, but seldom a marked leukocytosis. At the end of the operation, leukocytosis is usually present, and in almost all cases some increase beyond that found at the end of complete anesthesia. They observed that simple complicated fractures seldom increase the leukocyte count to any considerable extent. The blood after operation for malignant growths is not necessarily much impoverished, and regenerates normally. Especially interesting are the statements that very violent physical exertion produces in the blood a condition which leaves physiological limits, and approaches, or is identical with, that found in disease, and that a variation in the hourly leukocyte count exists in other conditions than the preperforative stage of typhoid, and may occur in health. This would seem to militate somewhat against the value of the hourly leukocyte count as an indication for operation in the condition of suspected typhoid perforation.

Unsuspected Trichinosis.—A very interesting paper by Williams has recently been published (*Journal of Medical Research*, June, 1901) in which he calls attention to the prevalence of trichinosis in the United States. We are concerned not so much with the interesting pathological findings in his cases, as with the fact that in the tissues of the 505 cases obtained at autopsy, from subjects in which there was no suspicion that trichinosis existed, the encysted parasites were found 27 times, that is, in 5.34 per cent. Practically, however, when we examine these statistics we find that in the cities of Buffalo and Baltimore 431 cases were examined with 17 positive results, and that of 57 cases coming from an institution in New York State, 9 were positive; that is, a proportion nearly four times as great. So that we assume that the average proportion of cases of this disease is really about 4 per cent. in our large cities. Now what can we infer from this? Are the Americans becoming like the Germans, feeders on raw pork, or are our ordinary methods of preparing pork insufficient to destroy the trichina parasites? These questions, of course, cannot be readily decided. There is no doubt that our German population maintains to a greater or less extent the habits of its native country, and naturally the increasing proportion of

this element should give an increased amount of trichinosis. When we examine the statistics we find that of the 27 positive cases, 6 were born in Germany, 2 in Italy and 7 in other foreign countries, that is, 55 per cent. of the whole number. The birthplace of one is not given; of the remaining 11 cases, 5 were negroes, 1 was a butcher, and 1 was an epileptic and dement. That is to say, we can assume that in the great majority of cases the victims of the disease were either foreign born, or persons whose habits or occupations were such as to render them exposed to the infection.

Williams has carefully collected the statistics on this point, and shows that as a matter of fact the white population of the United States has trichinosis less frequently than the colored population or the white population of other nationalities. The nationalities suffering most are the Canadians and the Italians, and the Germans are very close to them. Insane patients also appear to be more subject to the disease than others, but why this should be is very difficult to tell.

The paper is important because it seems to confirm the old Semitic objection to pork, and it warns us to be far more careful than we have hitherto been, to see that the flesh of the hog shall be thoroughly cooked.

The latest number of the *American Journal of the Medical Sciences*, under the able editorship of Dr. Francis R. Packard, of Philadelphia, comes to us enlarged. The publishers, Messrs. Lea Brothers & Company, of Philadelphia and New York, announce that this old and familiar periodical will henceforth contain about 200 pages of text or nearly 2400 pages per annum. It has been claimed for the *American Journal* that during the long period of its existence it has so fully represented medical science that a history of medical progress could practically be written from its pages. This is saying a great deal for any one journal. It is probably said as truly of this journal as it could be said of any in the world. We congratulate both the editor and the publishers upon this evidence of continued energy and vitality in the *American Journal*.

Current Comment.

QUACKS AND AN AMERICAN NEWSPAPER.

A Newspaper published in the United States, the *Philadelphia Times*, appears to have taken a step which should commend itself to all decent citizens in the district in which it circulates. It has published a statement to the effect that it declines to accept any advertisements that savour of quackery or fraud. We commend the *Philadelphia Times*, for the position it has taken up and we see no reason why a newspaper that has resolved to keep its columns free from degrading advertisements should not

give the fullest information as to its policy to the public for which it caters. In England there are many newspapers which do not publish advertisements of the class first referred to. These are, as a rule, newspapers circulating in classes of the community where such advertisements would not be tolerated or would not secure customers for the advertisers. The majority of newspapers in England which circulate among the lower middle and lower classes of society, and in circles where the credulous and the vicious are likely to form an appreciable element, almost invariably contain advertisements of the kind which the *Philadelphia Times* refuses to accept. It would be utopian for us to hope for the exclusion of quacks' advertisements from newspapers simply on the ground that they contain fraudulent promises of impossible cures and are the means of swindling simple-minded people. It is otherwise, however, when the advertisements deal with the results of sexual immorality and more or less openly proclaim the merits of alleged aphrodisiacs and abortifacients. Recent prosecutions have for a time caused a cessation of advertisement of the latter class; those of the former continue, and it will be remembered that it was the vendors of the female pills and concoctions who were prosecuted—not the newspaper editors who accepted their perfectly candid advertisements. Advertisements relating to venereal diseases and infirmities connected with sexual intercourse are in England declared indecent by Act of Parliament when exhibited near the highway or in public urinals. In newspapers their indecency would presumably be a question of fact for a jury, but the police do not institute proceedings in respect of them. That their suppression is desirable none will deny, for they are not only the product of vice and immorality—they are direct incentives.—*The Lancet*.

THE ABUSE OF THE DEFENCE OF INSANITY.

Nearly every one has enough of the milk of human kindness in his breast to be willing to concede that the taking of a human life under certain circumstances could have been none other than the work of a maniac, but it does grow wearisome to take up the paper day after day and find the plea of insanity entered as a matter of routine in murder trials. So commonplace, indeed, has such a plea become that it has for some time been the frequent theme of the paragrapher and the comic editor. We hear much from them of "The Insane Murderers' Trust" and like nonsense. Nor is this the only evil that has resulted. Only the other day, in a Massachusetts court, the jury deliberately sentenced to jail a murderer, who had been pronounced by experts both for the prosecution and for the defence a most dangerous paranoiac, on the ground that the public was tired of seeing criminals who had committed capital crimes temporarily confined in insane asylums and then allowed their full personal freedom to continue to menace the community. One learns with a sense of almost horror of such a decision and yet it is impossible not to feel that it is, in a sense, only the return of the boomerang cast by the hand of the alienist.—*The Medical News*.

Reviews.

Chronic Urethritis of Gonococcal Origin. By J. De Keersmaecker and J. Verhoogen. Translated and edited by Ludwig Weiss, M. D. New York: William Wood & Company, 1901.

In an introduction to this work by Oberländer, the reason for which is not plainly manifest, the statement is made that to arrive at a precise diagnosis of urethral inflammation and apply a rational therapy we must resort to urethroscopy. In the second introduction by the editor, which is of course eminently proper, the further statement is made that the urethroscope has proved to be indispensable to the specialist, and ought soon to become as favorite an instrument in the hands of the versatile practitioner as the otoscope or laryngoscope. The instruments employed by these authors are, however, so completely superseded by those of more modern construction that,

except for the admirable work done by the translator, this most modern work on a special subject would present the incongruity of ignoring the very devices that render this special study practical to the general practitioner.

The part devoted to the pathology of the subject is worthy of high praise. The descriptions are accurate and helpful. The treatment is, in the main, that generally applied by the majority of special workers in this branch of surgery. Special attention is paid to the use of Kollman's dilators, combined with irrigation. As a lubricant, it is noted that Gonyon's neutral soap is advised. This is not nearly so serviceable as certain moss preparations. There is a final chapter on gonorrhea and marriage, by the editor, which is characterized by the sound common sense and clear expression that everywhere mark his utterances.

The book closes, just before presenting some very fine illustrations, with conclusions that, as they are more or less authoritative, are worthy of being quoted:

Chronic gonorrhea of the urethra in man is an affection of invading character; its lesions are the result of the evolution of a neoplastic infiltration set up by the presence of the gonococcus.

The gonococcus may remain in the canal an indefinite time, and it is impossible to determine at what moment, the gonococcus having disappeared, the disease ceases to be transmissible.

The gravity of chronic urethritis results from the complications that may ensue in man and in others, especially women. It is therefore an absolute necessity to cure the disease in man. For this purpose there must be a precise diagnosis based upon complete methodical examination of the patient.

The nature of the pathological secretions, as to whether they contain gonococci, must be determined, and the origin also. Finally, exploration will be tried, using the well-known exploring instruments, having recourse also to the urethroscope. The only one of these instruments that seems to give results that are satisfactory is the urethroscope of Oberländer, but the newer urethroscopes with mignon lamps and without water-cooling device, are of course preferable (they are built after Oberländer's model).

The urethroscope must be relied on during the whole course of treatment, as it enables the operator to follow the course of the cure and to properly apply the principles of therapy. Dilatation is seemingly the only means of acting directly upon the fibrous infiltration that constitutes the essential lesion of chronic urethral gonorrhea.

By dilators the operator surely succeeds in setting up resorption of all the infiltration tissue capable of disappearing. The tissue not absorbed is transformed into indifferent cicatricial tissue, incapable of giving rise to recurrence or to transmission of the disease.

Complete cure is obtained by the dilators only when there is strict adherence to the rules for the use of them.

To declare a case of urethral gonorrhea cured, it must be shown that there is no longer any trace of purulent secretion (discharge, urinary filaments); that the canal no longer shows any kind of inflammatory lesion when examined through the urethroscope; and that the foci of infiltration, whose resorption has not been obtained, should have passed into the condition of indifferent cicatrices, as the end-stage of their evolution. [E. M.]

A Manual of Diseases of the Nose and Throat. By Cornelius Godfrey Coakley, A. M., M. D., Clinical Professor of Laryngology in the University and Bellevue Hospital Medical College, New York City; Laryngologist to Columbus Hospital, the University and Bellevue Hospital Medical College Clinic, and the Demilt Dispensary; Member of the New York Academy of Medicine, Society of the Alumni of Bellevue Hospital, Medical Society of the County of New York, American Laryngological, Rhinological, and Otological Society, etc., etc. Second edition, revised and enlarged. Lea Brothers & Co., New York and Philadelphia. 1901.

Dr. Coakley's Manual reviews briefly, though in a very satisfactory manner, the anatomy of the upper respiratory organs and the disorders to which they are liable. While a perusal of the work distinctly shows that the au-

tumor has prepared it for the student or general practitioner, one cannot but be struck by the wisdom embodied in many of the counsels given regarding the measures to be used. Rhinology and laryngology cannot be said to have advanced to any marked degree in recent years, unless it be in one direction, i. e., the proper limitation of operative procedures. Some years ago the saw, the snare and the cautery-knife constituted the ordnance with which the nasal cavities were attacked at whatever cost. As mere channels for air they could hardly be sufficiently widened to satisfy the needs of the organism. When, however, higher physiological functions were found to include the nasal mucous surfaces and the mucus itself, and when the very tortuousness of the canal was ascertained to be a desirable mechanical attribute of the protective functions of the portal of life—which after all the nose obviously is—a reaction occurred. Dry nostrils, foul breaths and adhesions which had become increasingly common among supposedly cured patients, also served to show that the nose had functions besides those of admitting, heating and dampening the air inhaled. Dr. Coakley stamps himself as a true specialist when he says: "We wish to caution the inexperienced against too active surgical interference. Many think that if a little cauterization or snaring gives a moderate amount of relief, more might be better. The result is a destruction of too much of the mucous membrane, thus leaving the patient with a condition of freedom so far as breathing is concerned, but with a dryness of the nose and throat very distressing and extremely difficult if not impossible to overcome." We are also pleased to note the conservatism which underlies the surgical treatment of the sinuses and the middle turbinate. Considerable may be done in these regions, but without entailing risks, especially when the lamina papyracea is involved, if for instance the curette is avoided and the alligator or punch forceps is used. Grünwald's punch forceps is very properly recommended for the purpose by the author—another detail which illustrates his true worth as an operator and teacher. Dr. Coakley's Manual is not only a very good book, but it is a *safe* book. [C. E. de M. S.]

The Pathology and Treatment of Sexual Impotence. By Victor G. Veckl, M. D. Third edition. Revised and enlarged. Philadelphia and London. W. B. Saunders & Co. 1901.

This is a thoroughly scientific work, and one, moreover, which bears evidence of much learning and which is written with rather a free hand. The author is never indelicate, but on the other hand he cannot be accused of an excess of delicacy. He never apologizes for his book (as so many writers on sexual subjects are apt to do) and we confess that we like him all the better for his frankness and independence.

The subject is a perfectly legitimate one for medical treatment; nay, it is highly necessary to have it well treated, and, provided an author does not descend to mere pruriency, he is under no obligation to make excuses for himself or to write with an affectation of modesty.

As we have said, Veckl's work is scientific, and based upon a large experience and an extended literary research. It is consequently not a book to be sniffed at, but to be frankly read, cogitated and digested. The subject is of perennial interest and importance to man and to woman. It is too much ignored in practice—a fact which will account probably for the surprise which most medical readers will feel when told by the author that sexual impotence in the male is a common affection. We protest that from our own experience in medical practice we should class it among the rare diseases. In its arrangement Veckl's book is strictly conventional; its value and its force consist in the individuality of the author's style, and in the fact that the subject matter is treated without undue reserve by a writer who has carefully studied it in all its phases. [J. H. L.]

Text Book on Nervous Diseases. By Charles L. Dana, A. M., M. D., Professor of Nervous Diseases in Cornell University Medical College, Visiting Physician to the Bellevue Hospital, Neurologist to Montefiore Hospital, Ex-President of the American Neurological As-

sociation, Corresponding Member to the Société de Neurologie, etc. Fifth edition, two hundred and forty-four illustrations. William Wood & Company, New York. 1901.

A text book which has reached a fifth edition in the comparatively short period of time which has elapsed since the first edition of this work appeared, surely does not need an extended review. The merits of Dr. Dana's work on Nervous Diseases are well known, not only to the specialist but to the general practitioner. We judge there is no book on nervous diseases in the English language which has been more frequently read and consulted. The present edition contains some minor changes throughout the text, but the most important addition has been a full chapter on general paresis. There is also a practically rewritten chapter on myelitis. Other necessary changes and some corrections have been made, but the size of the book is not materially increased. We congratulate the author upon the favor with which his book has been received and we bespeak for it a continuation of patronage by the profession. [J. H. L.]

Perinephritic Abscess.—Not only is perinephritic abscess rare, but it may exist without being even suspected. Besides, the diagnosis is very difficult. Perinephritis may be primary, or secondary to an affection of the kidney or of some other near-by organ, or to an infectious disease. Perinephritic abscess is generally seen in adults of the laboring classes. Traumatism, renal lithiasis, and disease of the kidney or any of the neighboring viscera may cause it. Or typhoid fever, septicemia, etc., may produce perinephritic abscess. Infection may reach the perinephritic tissues by the blood vessels, in the infectious diseases, by the lymph vessels, from near-by foci of suppuration, or by the urine, from a kidney affection. Dr. E. Verstraete, in discussing this subject before the Société Anatomique-clinique de Lille, (*Journal des Sciences médicales de Lille*, June 1, 8, and 15, 1901) divides perinephritic abscess into partial or total; also into retrorenal, suprarenal, or subdiaphragmatic, and anterolateral or subrenal abscess. It may open in the pleura or bronchi; in the iliac fossa, along the psoas; in Petit's triangle; or in the umbilicus. During onset the symptoms are deep lumbar pain, radiating in many directions, or a vague pain occasionally. There may be fever, or no general symptoms at all. About two weeks later a swelling is felt in the lumbar region, with great tenderness, and a decidedly hectic temperature persists. Until the tumor appears, diagnosis may be impossible. The prognosis is generally favorable. As a rule, a lumbar incision, with evacuation of the pus, and drainage, results in recovery in a few months. The histories of six cases of perinephritic abscess follow in full. Of these, 4 recovered, one died, a man of 67, and in one the condition recurred eight months after operation. [M. O.]

On the Restriction of Tuberculosis in Western Europe and America.—F. M. Blumental, in a paper read before the section of bacteriology of the Imperial Society of Natural Science, Anthropology and Ethnography (*Russki Archiv Patologii, Klinicheskoi Meditsiny i Bakteriologii*, March, 1901), pointed out that while the Franco-Prussian War (1870-1871) cost Prussia 40,950 men, tuberculosis destroyed during the same period 80,000 lives. In Moscow 1475 persons died of cholera from 1892 to 1894, inclusive, while the number of deaths from tuberculosis reached 10,650, i. e., 7 times more. In Europe, except Russia, the mortality from tuberculosis is one million annually; in Russia 360,000-450,000. Statistics show that the majority affected are in the prime of life, between 20 and 40, and that three-fourths of the victims are recruited from the laboring class. Regarding the financial loss sustained, it is found that Germany, with a mortality from tuberculosis of 89,000 in 1894, lost 370,000,000 marks, and France about half-a-million francs. In the fight against tuberculosis the following three propositions should be accepted: 1. Tuberculosis is infectious; 2. It is preventable and curable, and 3. all measures undertaken for its restriction should be thorough. Thanks to the wise sanitary measures and the establishment of special sanatoria, England, as well as New York brought about a marked decrease in the mortality from tuberculosis. [A. R.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Society Meetings Next Week.—The following societies will hold meetings next week at the College of Physicians, at 8.15 P. M.: Monday evening, November 11, Section on Medicine, College of Physicians; Tuesday evening, November 12, Pediatric Society; Wednesday evening, November 13, Philadelphia County Medical Society; Thursday evening, November 14, Pathological Society.

The Municipal Hospital to be Sold.—On October 30, the Councils Committee resolved that the grounds of the Municipal Hospital of Philadelphia be advertised by the city for sale, and the site abandoned for a more isolated one in a less populated section of the city. The chairman of this committee will introduce the resolution to that effect in Councils. It was reported that some years ago an offer of \$250,000 was made for the ground now occupied by the hospital. A committee was appointed to consider the purchase of property for the new municipal hospital.

A Temporary Smallpox Hospital.—The committee in charge of arrangements for the Meschianza, which is to be held at the Academy of Music November 11 to 16, for the benefit of the McKinley Memorial Hospital, has taken an important step toward fulfilling the object of their mission. A large plot of ground has been secured near Fort Mifflin, in the lower section of the city, upon which a temporary hospital will be erected for the treatment of smallpox and other contagious diseases.

A New Miners' Hospital.—At a meeting held last week at Pine Grove, Pa., a committee was elected for the purpose of petitioning the Legislature for the establishment of a Miners' Hospital on the summit of Broad Mountain, ten miles north of Pine Grove. The territory appealing for this relief are the miners from the Lykens, Williams, Pine Grove, Tremont and Swatara Valleys, being parts of Dauphin, Lebanon and Schuylkill counties, and comprising a population of about 50,000 people that need hospital service. The miners claim that lives have been lost and injured men required to endure intense suffering until the Miners' Hospital at Ashland is reached.

A Needle's Journey.—After carrying a portion of a needle in his body for twenty-six years, a resident of Berwick, Pa. had the tiny bit of steel removed from his left arm. When the needle first entered his body, it ran into his right leg below the knee. At that time a portion of it was removed. At various times since then he has been troubled with pains that he thought were caused by rheumatism, but which are now supposed to have been caused by the needle.

Smallpox.—During the week ending November 2, there were 52 cases of smallpox reported in the city of Philadelphia, with 12 deaths. While there is no increase, there seems to be but a slight decrease in the present epidemic. A number of cases have been discovered in the vicinity of Philadelphia, six cases being reported from Bryn Mawr, where the hospital and five houses are in quarantine. The State Insane Asylum in Norristown has decided that every physician, employé and patient in the institution must immediately be vaccinated.

Diphtheria in Greenfield, Pa.—In Greenfield, twenty miles from Corry, seven deaths are reported from diphtheria. Failure to use antitoxin early is supposed to be the cause of the spread of the disease. The place is quarantined.

Philadelphia Polyclinic Appointments.—At the meeting of the Board of Trustees of the Philadelphia Polyclinic and College for Graduates in Medicine, held on October 29th, Dr. John H. Gibbon was elected Professor of Surgery, to succeed Dr. T. S. K. Morton, who was appointed Emeritus Professor in this department. Dr. Samuel McC. Hamill and Dr. James H. McKee were elected professors of diseases of children.

German Hospital Election.—At a meeting of the Board of Trustees of the German Hospital, October 29th, Hermann Hessenbruch was unanimously elected to fill the

office of president, made vacant by the death of John D. Lankenau on August 30 last. Colonel M. Richards Mucklé was re-elected vice president. The other officers are: secretary, the Rev. F. Wischan; treasurer, Charles A. Wörwag; solicitor, Joseph G. Rosengarten. Mr. Hessenbruch comes of a German family, originally of Halwer, Pomerania. The family moved to Itterscheidt, Düsseldorf, Prussia, in the centre of the German steel and iron industry, in 1700, and there the cutlery business was established that has been conducted by the family for three generations. Mr. Hessenbruch was born in Philadelphia, June 20, 1846, his father, Gottlieb Theophilus Hessenbruch, having come to this country in 1836. After being educated at the Zane street grammar school in Philadelphia, and after spending two years in Germany and a year in Belgium, he returned to this country, and was admitted to business with his father in 1870.

Free Hospital for Poor Consumptives.—In an appeal sent out by the Board of Managers of the Free Hospital for Poor Consumptives over the signature of Dr. Fllek, president, they say: "We have forty patients, in various hospitals, for each of whom we pay \$5 a week. We have two female patients in the Adirondacks, for each of whom we pay \$7 a week. We have twenty male patients in our camp at White Haven, who stand us about \$5 a week per patient. Our expenses aggregate about \$1300 a month. The State gives us about \$400 a month, and we are compelled to raise \$900 a month from the charity of the people. Our treasury is empty. The forty dying patients are given a decent place in which to die, and we are abating forty centres of distribution of tuberculosis. Ninety per cent. of the twenty cases at White Haven we believe will recover, and return to lives of usefulness. In August their gain was twelve pounds per patient; in September, seven pounds per patient. Four patients have returned to work. It is certain that tuberculosis can be cured, but money must be provided." Edward A. Millar, 404 Walnut street, is the treasurer.

Vital Statistics of Philadelphia for the week ending November 2, 1901.

Total mortality.	415	Cases.	Deaths.
Inflammation of the appendix 1, brain 10, bronchi 5, heart 6, kidneys 21, larynx 1, liver 3, lungs 47, pericardium 1, peritoneum 3, stomach and bowels 14.			112

NEW YORK AND NEW JERSEY.

New York State Antitoxin Laboratory.—The State Antitoxin Laboratory in Albany, of which Dr. H. D. Pease, of Yale University, has been appointed director, has secured a good building. The animal house for the manufacture of serum will hold 15 horses. It is proposed to supply antitoxins to the State institutions and to such municipalities as are not already provided with a similar laboratory. Thus all the health officers in the State will have the same facilities for the investigation, diagnosis and treatment of infectious diseases as are now supplied by the City of New York.

Czolgosz's Body.—The fact that Czolgosz's body was buried in sulphuric acid and quicklime has roused the ire of the chemists, for an equal quantity of these substances will exactly neutralize one another. Yet any excess of either material will rapidly destroy the body.

Poisoning from Doughnuts.—From New York comes the news that twenty people were poisoned by eating crullers and doughnuts purchased at a certain bakery on Tenth avenue. The baker had used a new baking oil the day before. None of the cases proved fatal.

New York Skin and Cancer Hospital.—The Governors of the New York Skin and Cancer Hospital announce that a fourth series of clinical lectures on diseases of the skin will be given by Dr. L. Duncan Bulkley in the Out-Patient Hall of the Hospital on Wednesdays afternoons, at 4.15 o'clock. The course will be free to the medical profession.

NEW ENGLAND.

The New Hospital for Consumptives, Boston, Mass.—The trustees of the pauper institutions on Long Island are building a new hospital, in which, when it has been completed, all those suffering from tuberculosis will be placed, thus separating them from the other patients under treatment. The plans show a building with two long wings, connected by a central building. Two lobbies lead into a corridor in each wing, and on either side are nurses' rooms. At the end of each corridor is a ward the full width of the wing, with a sun room attached, lighted by five windows. Back of the lobbies is a central kitchen with a dining room on either side. The main entrance, opening into the corridors, has an octagonal front porch with southern exposure. Over this porch is a third sun room, with a large women's ward behind it. Only the central pavilion has a second story. The wings are to be at a right angle to one another, joining the central building obliquely.

Tribute to Dr. S. G. Howe.—The hundredth anniversary of the birthday of Dr. Samuel Gridley Howe will be celebrated in Tremont Temple, Boston, on Monday, November 11th, at 3 o'clock P. M. Senator Hoar has consented to preside on the occasion, and addresses are to be made by surviving personal associates of Dr. Howe. A romantic, chivalrous and philanthropic life of rare usefulness is to be commemorated. The memory of what Dr. Howe did, his earnestness and usefulness in forwarding good work are inspiring, and the presence at this gathering of the blind people, with the welfare of whom his name is inseparably connected, will be a touching feature of its proceedings.

The Purity of Ice.—H. W. Clark, at the meeting of the associated boards of health of Massachusetts described the purity of ice. It was long a popular notion that water purifies itself in freezing. But the discovery, in recent years, that, while all microbes perished from a moderate degree of heat, there were forms that survived the most intense cold, brought the idea into disrepute. Clarke's researches, however, show that the old notion was very nearly correct. He shows that in crystallization ice exerts a force of expulsion, not only upon bodies held in suspension, but also upon a large percentage of those held in solution. Hence, ice is not only likely to be free from bacterial impurities, but the melting of ice formed from water that is hard or salt produces water that is comparatively

soft and fresh. It is important, however, that we should understand that ice is thus purified only when there remains a considerable proportion of water not frozen. The rejected impurities accumulate in this water. And the deeper and stiller the water, the purer the ice. When the entire body of water is frozen, the impurities are naturally included. If ice is flooded with impure water to make it thicker, it naturally, likewise, becomes impure, and may be correspondingly dangerous to health. But there appears to be comparatively little danger from the pollution of an ice supply, and instances of disease from such sources are exceedingly rare.

WESTERN STATES.

The University of California.—Beginning in 1905, the Medical Faculty of the University of California will demand at least two full years of college work from all applicants for admission. These two years must have included advanced work in chemistry, physics, and zoology, with sufficient English and scientific French and German. In a circular recently published, it is suggested that students expecting to matriculate in 1905 or later also do some preliminary work in advanced mathematics, comparative anatomy, embryology, chemistry, and physics. A broad foundation in general culture is advocated as a forerunner to one's medical education. From perusing this circular, the fact is plainly shown that the great universities of the West are closely following the high standard set by those in the East.

Rocky Mountain Industrial Sanatorium.—This sanatorium for consumptives has been in operation for one month, five miles southwest of Denver, Col., with which it is connected by electric railway. While there are at present but 15 patients, as many as 35 will shortly be admitted. Patients are obliged to pay only for the actual cost of living, and will be given the opportunity to take part in remunerative industries. There are satisfactory buildings for present needs, an orchard of five acres, garden ground, and a good water supply for irrigation. The medical director is Dr. A. M. Holmes.

Tetanus in St. Louis.—One dozen deaths attributed to lockjaw have occurred in St. Louis as a result of the administration of diphtheria antitoxin manufactured by the city chemist. Eleven other children are reported to the Health Department as suffering from lockjaw, with slight chances for recovery. The cause of tetanus in each case is said to be poisoning from the city's diphtheria antitoxin. The Health Department of St. Louis has begun the free distribution of tetanus antitoxin for injection into the blood of diphtheria patients who have been inoculated with the infected serum and thus exposed to lockjaw. No more diphtheria antitoxin will be manufactured by the city of St. Louis. The investigation ordered by the City Coroner to determine positively the cause of the deaths of the eight children who are alleged to have died of lockjaw, following the administration of the city's antitoxin, is being pushed. Doctors Bolton, Fish, and Waldron, three of the most experienced bacteriologists in St. Louis, are making tests with the anti-toxin and the serum taken from the spinal columns of the dead children. Dr. Ravold, city bacteriologist, who made the antitoxin from serum taken from a horse which developed tetanus on October 1 and was shot, declares that if the animal's system contained tetanus bacilli on August 24, when the last serum was taken from it, it was impossible to detect it by an inspection of the horse. At the Baptist Hospital an independent investigation has convinced Drs. A. B. Nichols, R. C. Harris and C. C. Morris that the presence of tetanus germs in the city antitoxin is indisputable. A guinea pig, inoculated with the antitoxin Wednesday night, developed symptoms of lockjaw Thursday morning and died next day.

Asylum for Insane Indians.—An asylum for insane Indians has just been completed at Canton, S. D., at a cost of \$55,000.

Ears Bought for \$300 Apiece.—Dr. E. E. Prescott found two men in Chicago, each of whom signified his willingness, in answer to an advertisement, to part with one ear for a consideration of \$300. The ears are necessary for an unusual operation the physician hopes to perform. Obstacles in the case of criminal responsibility, however, presented themselves to Dr. Prescott, for Justice Blume in-

formed him that if he covered a healthy ear from the head of any person, knowing that he would thus deform that person, he would be guilty of mayhem. The physician immediately went to State Attorney Deneen regarding his responsibility in such a case. The prosecutor told him that in his opinion he would be guilty of no crime. The two persons who will sell their ears as sacrifices to this operation are widely different, both in age and appearance. One of them is a paralytic nearly sixty years of age.

Smallpox Destroys Indians.—Late reports from the Winnebago Indian Reservation in Nebraska show that 53 of the 1000 Indians on the agency have died of smallpox. As the medical force of the reservation is limited, the epidemic of smallpox threatens the destruction of the entire tribe.

CANADA.

Two New Fellows in Pathology.—Dr. G. A. Charlton, of Montreal, and Dr. P. G. Wooley, of Johns Hopkins University, have been appointed fellows in pathology at McGill University. The former is a graduate of McGill, while the latter claims John Hopkins as his "alma mater." Both will assist Dr. Adam, professor of pathology; and their special work will be to discover means to combat the spread of infectious diseases. Dr. Ford, some time ago appointed to the Rockefeller research scholarship at McGill, who has been studying for several months at the Pasteur Institute, Paris, will shortly return to McGill. The pathological department, which has been undergoing extensive alterations and additions, will soon be ready for taking up this research work.

The Science Faculty at McGill has raised its standard, the following notice having been placed upon the college boards: "It has been decided by the Faculty that the number of marks required for pass-standing in any subject shall be forty per cent.; for second-class honors, sixty per cent.; for first-class honors, eighty per cent. The change is said to be unpopular among the 300 odd students of the Faculty of Applied Science, but it is only a precursor of what is to happen in the other faculties in the near future. In the Faculty of Medicine the course at present consists of four sessions of nine months each, which will soon, in all probability, be raised to five sessions of nine months each.

An Extensive Outbreak of Smallpox is reported from Ottawa. Something like forty cases developed before October 26; and there has been a good deal of excitement, interference with business, and anxiety on the part of the citizens of the Capital. Dissatisfaction with the Medical Health Officer, Dr. Robillard, became so pronounced that the local Board of Health had to ask for his resignation. This was acceded to after some delay and Dr. Law, of the same city, appointed as his successor. A general vaccination has been prosecuted, and the outlook for prompt limitation of the scourge seems to be good.

Canadian Medical Graduates and the Imperial Army is a subject which has again come to the fore on account of an announcement by cable that a Canadian medical graduate had been refused permission to serve on the British medical staff in South Africa. Only a few months ago the Militia Department was notified that a measure had been introduced into the British House of Commons which would provide for the entrance of graduates of recognized colonial medical colleges into the Imperial army, naval, and civil services. What became of this measure, military surgeons are now asking in view of the cable announcing that one of them has been set aside as a candidate for one of these positions.

The Birth Rate in Ontario is being vigorously assailed by the Anglican clergy. Three years ago the Committee on Vital Statistics of the Provincial Synod of the Anglican Church, which has jurisdiction over the Maritime Provinces, Ontario and Quebec, was instructed to prepare a report on the three questions of the birth rate, infant mortality in Quebec, and tuberculosis. This Committee brought in a report at the recent meeting at Montreal, from which it would appear that the birth rate has gradually declined in both Quebec and Ontario for the past four years, returns not being available from the other provinces. For instance, Ontario has decreased from 20.7 in 1896 to 19.4 in 1899; while Quebec has come down from 38.57 to 33.46. Ontario has a birth rate lower than that of any European

country, but not lower than some of the neighboring States, notably Michigan and New Hampshire. The committee state that the cause of the ever decreasing birth rate in this province is the use of preventives, information as to which is spread far and wide by advertisements in the public press and otherwise. They advise that the Bishops be requested, in their pastorals, to call the attention of the people to the Divine and social purposes of marriage, and to the awful sin of interfering to prevent the procreation and birth of children. This advice is already being carried out; and it may be expected that the Anglican clergy will become a powerful factor in the elimination of this class of advertising from the public press, a condition which has become too common.

University of Toronto.—It is announced that Professor Goldwin Smith has given \$10,000 to the trustees of the University of Toronto to be expended upon the library. As the University is in need of funds, it is to be hoped that this example will be followed by others.

MISCELLANY.

Yellow Fever in Yucatan.—Advices were received by the Marine Hospital Service from Alabama last week that yellow fever is now epidemic throughout Yucatan. The disease prevails among the Yucatan Indians from whom it has been contracted by the Mexican troops sent to fight them. The report says the Government cannot prevent the introduction of the fever into New Loel through lack of railroad facilities.

The World's Mortality.—Statistics show that 33 millions of people die every year throughout the entire world, an average of 91,534 a day, 3730 an hour, and 62 every minute. The average length of human life is 36 years. One quarter of the world's population dies before reaching the age of 7 years, and one half before becoming 17 years old. Out of 100,000 people, but one reaches the age of 100. Of 1000 people who reach the age of 70, 43 are clergymen or politicians, 40 are farmers, 33 workmen, 32 soldiers, 29 lawyers or engineers, 26 professors and but 24 physicians.—*Journal de Medecine de Paris.*

Average length of Life.—We are rapidly gaining in the average length of human life. Better sanitation, the enforcement of precautions against contagious and infectious diseases, and the advancement of surgery and medicine, are causing an even more rapid reduction of the death rate than the layman might guess. The census bulletin of deaths that occurred in 271 cities of 5000 population or more shows that 18.6 persons died in 1900 out of every 1000, whereas in 1890 the number who died in the same cities was 21 out of every 1000. The average age at death in 1890 was 31.1 years; in 1900 it was 35.2 years. If these statistics be accurate, the saving of human life that has been achieved in a decade is enormous.

Smallpox in Alaska.—The captain of the revenue cutter Bear, who has just returned from Bering Sea, brings reports of the havoc wrought last year by an epidemic of smallpox. Not more than half of the population survived. In the asylum at Golovin and Port Clarence there are 45 orphans, whose parents were victims of last season's epidemic.

There are about 2,500 hospitals and asylums in the United States. These give employment to 65,000 people and pay over \$23,000,000 in salaries. These hospitals have 300,000 beds, are attended by 37,500 physicians, and treat over 1,000,000 patients during the year.—*Cleveland Medical Gazette.*

Obituary.—Dr. J. Mortimer Crawe, Sr., at Watertown, N. Y., October 29, aged 70 years—Dr. William M. Hudson, at New Haven, Conn., October 30, aged 68 years—Dr. A. B. Purrington, at Bell Center, Wis., October 31, aged 79 years—Dr. Benjamin H. Bradshaw, at Salem, Oregon, October 14, aged 67 years—Dr. George B. Bunn, at Mount Vernon, Ohio, October 22—Dr. William J. Kearney, at Mariposa, Cal., October 10, aged 45 years—Dr. Albert Binder, at Ottoville, Ohio, October 22, aged 38 years—Dr. Louis D. LaBonte, at Derby, Conn., October 21, aged 31 years—Dr. William Geddes at Washington, D. C., October 21, aged 50 years—Dr. Charles Edward Dority at Brooklyn, N. Y., October 23—Dr. Gustavus E. Gramm, at Philadelphia, Pa., on November 2, aged 78 years—Dr. E. P. Lowther, at Martinsville, W. Va., November 2—Dr. Garrett D. Van Vranken, at Hempstead, L. I., November 1, aged 60 years.

GREAT BRITAIN.

The Plague in Great Britain.—Toward the end of October several cases of bubonic plague were discovered in Liverpool. While these cases were at first thought to be influenza, bacteriological examination after death proved that the patients had the plague. Six deaths of supposed plague have occurred in Liverpool since September 3. No new cases have developed this month. At the same time the plague reappeared in Glasgow, where four cases were discovered in a hotel. That these cases were true plague was also proved bacteriologically. From Brisbane, Australia, comes the news that the plague has reappeared, though there had been no cases reported during August and September.

Bristol Royal Infirmary.—On October 25, 1901, the new bacteriological department of the Bristol Royal Infirmary was opened. Sir Frederick Treves, K. C. V. O., C. B., delivered an address, and presided at the annual dinner of the Medical School afterward.

Statistics Obtained by Antityphoid Inoculation in Dublin.—Statistics made during the epidemic of typhoid fever which occurred in Dublin last winter show the great immunity of those people who had been inoculated with antityphoid serum. In 501 persons under 55 years old, who were inoculated, no cases of typhoid occurred, while in the 114 uninoculated five cases occurred. Another list shows that while 30 cases occurred among 298 uninoculated, out of 339 inoculated but five cases occurred.—*Lancet*.

Outbreak of Typhoid Fever.—A serious outbreak of typhoid fever is raging in the East Northumberland mining districts, many hundreds of cases being under treatment.

New Sanatorium for Consumptives.—On October 18th the new sanatorium for consumptives in Delamere Forest, Cheshire, which cost £15,000, was opened. This will be used in connection with the Liverpool Hospital for Consumption and Diseases of the Chest.

Obituary.—On October 14th, by the death of Dr. James Foulis, Edinburgh has lost one of its most successful physicians. Born in 1846, at Sydney, New South Wales, he was graduated at the University of Edinburgh in 1874. His most important work was upon diseases of the ovary. Lately he took an active interest in the question of the transmission of infectious diseases by milk. He died of cardiac disease aggravated by influenza.—From Belfast comes the news of the death of Dr. Hugh Fisher, on October 18th, aged 31 years.—On October 16th Dr. R. B. McClelland, who graduated at Glasgow University in 1849, died at Banbridge, Ireland.—Charles King, M. R. C. S., died recently in London, aged 76 years. He was a graduate of Guy's Hospital.—On October 20th Henry Duncalfe, M. R. C. S., died at Droitwich, aged 73 years. He was a graduate of Guy's Hospital and was former president of the Birmingham and Midland Counties of the British Medical Association.

CONTINENTAL EUROPE.

Nothnagel's Sixtieth Birthday.—Though Professor Nothnagel was sixty years old on September 28th, the celebration of his birthday only occurred on Sunday, October 13th, when his portrait, painted by Horowitz, was presented to the Professor by his friends and former students. Dr. von Kogerer delivered the address of presentation. Hermann Nothnagel has been professor of medicine and director of the First Medical Clinic in the University of Vienna for years. The *Wiener klinische Wochenschau* published a "Festnummer" in his honor, containing the work of six assistants of the Nothnagel Clinic.

Typhoid Fever in Germany.—A severe epidemic of typhoid fever has been raging in the province of Westphalia, Germany, for the past six weeks. While the death list is comparatively short, the total number of patients reaches far into the thousands. In the centre of the affected district are the towns of Gelsenkirchen, Bochum and Lünen-scheid.

Fiftieth Anniversary.—Dr. Wanjura, Privy Sanitary Councillor in Berlin, celebrated the anniversary of the completion of his fiftieth year in medicine on October 6, 1901.

The Plague at Naples.—Dr. Santoliquido, chief of the health department, of the Ministry of the Interior, spec-

ially delegated by the government to direct and supervise measures dealing with the disease when its presence was discovered in Naples, made the following statement: "It is quite true that there have been several cases of bubonic plague here recently, but it is an exaggeration to characterize the matter as epidemic. From first to last, fifteen persons were attacked. Out of these, eight deaths occurred. At the present moment there is not a trace of the plague in the neighborhood. Within three weeks from the discovery of the first case, the disease was completely mastered." Dr. J. M. Eager, of the United States Marine Hospital Service, medical attaché to the United States Consulate, calculated that the number of cases has been about twenty. Dr. Eager and his staff examine all emigrants leaving Naples for America, disinfect their belongings and even take the temperature of all would-be emigrants. Those whose temperature is above normal are detained and kept under observation.

A New Treatment for Seasickness.—Dr. Heinz, professor of therapeutics at the University of Erlangen, advises long, deep, and quick breathing for curing seasickness. He believes that one cerebral lobe is affected, and that this influences the stomach. Oxygen rapidly reaches the blood by drawing deep, long and quick breaths, and the feeling of nausea disappears. His experiments upon people have been very successful.

The Second International Congress of the Medical Press.—At the first International Congress of the Medical Press, held in Paris last year, it was decided to hold the second annual congress in Brussels during 1901. The Committee appointed last year has determined to postpone the second International Congress of the Medical Press for another year. In the meantime delegates from the entire world will be chosen, and a constitution prepared. The president of the Committee is Dr. L. DeJace, of Brussels, and Dr. V. Pechère is secretary.

Germans Taught Hygiene.—The German government has instructed the Berlin Hygienic Association to open offices in which instructions on hygiene and sanitary matters shall be imparted gratis. Doctors will be present at certain hours every day to answer questions as to the best food to eat, the best clothing to wear in the different seasons, and questions on housing, cooking, heating, sleeping accommodations; whether children should be washed with hot or cold water; what outdoor exercises are best at various seasons; how long children should remain out of doors; how to protect one's self against colds, influenza, etc.

Malarial Poison as a Cure for Cancer.—Injections of malarial blood as a cure for cancer are proposed by Professor Friedrich Löffler, of Greifswald. Finding that amid tropical condition most conducive to malaria cancer is of extreme rarity, he was led to the conclusion that, when malaria is administered, it acts as an antidote to cancer. What he calls the remarkable infrequency of cancer among negroes in the United States and other African populations is cited as one of the chief supports for his theory. It is established that malaria, when artificially produced by hypodermic or internal injections of the blood of malarial patients, can be arrested by prompt administration of quinine. He suggests the inoculation of cancerous persons with mosquito poison or the blood of patients afflicted with other malarial infections. Previous attempts to cure cancer through vaccination with infectious substances have not only been crowned with little success, but have been accompanied by great danger, because of inability to control the antidote. In tropical lands where malaria flourishes cancer is seldom known. In Borneo, after ten years of close observation, not a single case was discovered.

Obituary.—On October 15th Dr. Oskar Wilhelm Stelzner died in Dresden, aged 62 years. Dr. Stelzner has been surgeon to the Dresden City Hospital for over thirty years.—The death is announced of Dr. Marcel Nencki, professor of medical chemistry and bacteriology in the Institute of Experimental Medicine in St. Petersburg, at the age of 55 years. Dr. Nencki was formerly professor of medical chemistry in Berne.

1.—The satisfactory termination of many cases of exploratory incision into the kidney for various suspected lesions which were not found at the time of operation leads Harrison to infer that renal tension has been the cause of the symptoms and that the relief of this tension by incision has been responsible for the good results, just as marked mitigation follows iridectomy for glaucoma, and orchitis subsides after puncture or limited incision. It is not to the study of dead kidneys, but rather to the palpation and inspection of the living organ in situ, that the conviction of the importance of tension in the production of some of the conditions which are included in the term of Bright's disease, is due. Six cases are cited in which incision was followed by recovery. One was scarlatinal nephritis, one a nephritis from exposure to cold, one a sub-acute nephritis subsequent to influenza, one a nephritis associated with injury, and one a cystic degeneration of the kidneys developing after trauma. "The following may be regarded as some indications for relieving tension sur-

gically in cases of nephritis, however arising: (1) Progressive signs of kidney deterioration, as shown by the persistence or increase of albumin when it should be diminishing or disappearing from the urine, as in the natural course of inflammatory disorders ending in resolution; (2) marked suppression of urine or approaching this state; (3) where a marked disturbance of the heart and circulatory apparatus arises in the course of inflammatory renal disorders." The author prefers making the incision along the convex border of the kidney; punctures may be made wherever the congestion seems greatest, but it is well to avoid the pelvis of the organ. Drainage is essential, a rubber tube usually remains in place from a week to ten days. The question as to which organ should be selected for incision is of little importance unless there be marked pain or some other definite indication for one side or the other, as division of the capsule of one kidney reflexly lowers the tension in its fellow. Spanton reported two cases in which complete recovery followed exploratory incision of the kidney for the calculus in which no stones were found. He believes the best subjects will be those who present a subacute nephritis. Cousins thinks the most favorable cases for surgical measures are the acute inflammations associated with infection through the blood. Barling said that the majority of cases of renal tension were bilateral, and that they could only be relieved by medical measures and local treatment, such as cupping, applicable to both sides. Chicken deprecates the opening of the capsule for high tension alone. [F. T. S.]

2.—Hutchinson states that the X-rays (except in stout subjects or in the case of very small stones) enable an exact diagnosis as to size, position, and number of renal calculi, to be made; they enable the surgeon to remove stones with the least possible injury to the kidney and dispense with bringing the organ to the surface of the wound. Limited incision over the calculus through the renal pelvis should be preferred, as they heal as well as wounds of the parenchyma. Urotropin is advised before and after the operation to render the urine healthy. Renal stones, however small, should be operated upon as soon as the diagnosis is made; the damage which they may inflict bears no relation to their size. [F. T. S.]

3.—Bramwell's patient was a widow, aged 49 years who had suffered with indigestion for 19 years. The right kidney was movable, a mass could be felt in the region of the pylorus and the stomach was dilated. She died from syncope owing to a sudden increase in the size of the stomach from gas distension. At autopsy an enormously dilated stomach with walls as thin as paper was found. Three cords of thickened peritoneal tissue extended from the pylorus to the surface of the kidney, which was movable to the extent of 3 inches. The peritoneum was firmly attached to the kidney, and descent of the organ clearly dragged on the duodenum and pylorus, causing stenosis. [F. T. S.]

4.—Parry proposes a new operation for the cure of femoral hernia. A curved incision with the convexity downward is made from a little external to the pubic spine to the middle of Poupart's ligament and the flap of skin raised. The inguinal canal is opened just above Poupart's ligament and the transversalis fascia divided. A catgut suture is passed through the fundus of the sac, then through its neck, and finally through the conjoined tendon and transversalis fascia so that when it is tightened, the sac disappears within the abdomen. The conjoined tendon is now attached to Gimbernat's ligament and Cooper's ligament by two sutures of catgut, thus closing the crural opening. Two or three sutures fix the conjoined tendon to Poupart's ligament to strengthen the inguinal canal. Fifteen cases have been operated upon by this method, 6 were under observation for 3 years and 5 for over 2 years without recurrence being noted in any. [F. T. S.]

5.—Brown extols the value of intravenous injection of salt solution in the treatment of shock and hemorrhage. [F. T. S.]

6.—Barling says the conditions which may call for operation during the course of gastric ulcer are: Fulminating hemorrhage; recurrent hemorrhage; pain, vomiting and loss of weight; stenosis of the pylorus with dilatation of the stomach; and adhesions interfering with the motility of the stomach. There is little encouragement for the operative treatment of fulminating bleeding and we should rely on medical measures. For recurrent bleeding the ulcer may be excised or cauterized, or an anastomosis may be

made between the stomach and the jejunum; the author seems to favor the latter. In the treatment of stenosis of the pylorus, pylorodiosis should be abandoned; pyloroplasty is suited to cases in which there is not much thickening of the parts, and when adhesions are not present. In performing gastro-jejunoostomy the author has always employed the anterior method by using the Murphy button. The button has been retained in all of the cases, but has never given rise to any disastrous results. Heaton claims that anterior gastroenterostomy is the better operation when an anastomosis is desired, as it may be quickly performed, and thus gives a lower mortality. Bidwell analyses 14 cases of gastric dilatation consequent to ulcer of the stomach. In 8 the pylorus was contracted from scar tissue; in 2 the dilatation was due to adhesions; and in 4 spasm of the pylorus was present. There were no operative deaths. When operation is undertaken during actual ulceration, Bidwell prefers gastro-enterostomy if the ulcer is situated near the pylorus, and pyloroplasty if it is in a distant part of the stomach. For spasm of the pylorus, dilatation by invagination is curative; when the stenosis is due to cicatricial contraction, gastro-enterostomy is the best procedure. White argues that gastro-enterostomy is applicable to all cases of pyloric stenosis, can always be effected through healthy tissues, the parts may be withdrawn from the peritoneal cavity and carefully isolated with pads, it has fewer failures than pyloroplasty, and the mortality is no higher; it is the better operation for the majority of cases. Morton recorded a case in which recovery followed gastro-enterostomy for ulceration. Morison expressed views similar to those of Barling. Bush believes stretching the pylorus will be gradually less performed. He attached great importance to early operation. Parry related the histories of two cases of gastric dilatation following pyloric stenosis and treated by pylorotomy. Both cases made an excellent recovery.

[F. T. S.]

7.—Ferguson reports a case of **perforation of the stomach** by an ulcer in a woman aged 25. There had been previous gastric pain. At operation the perforation was found on the posterior wall of the stomach just to the right of the esophagus and 2 inches below the lesser curvature. It was inverted with Lembert sutures and the peritoneal cavity wiped dry with gauze. Recovery followed.

[F. T. S.]

8.—Beatson reports an inoperable **carcinoma of the breast treated by oophorectomy and the administration of thyroid extract** in a woman aged 44 who had suffered from the growth for 1½ years. Six months after the operation the mass had almost entirely disappeared and the enlarged glands in the axilla and above the clavicle could no longer be palpated. The diagnosis was confirmed by microscopic examination. The operation is not advisable when metastasis has taken place. Barling did not think the operation could be substituted for the ordinary operative procedure. Chicken recommended that the ovaries be removed coincidentally with the primary growth, and that the operation need not be confined to inoperable cases.

[F. T. S.]

9.—Herman reports the results in 8 cases of **oophorectomy for cancer of the breast**. One is free from cancer at the end of 3 years, in 2 life was prolonged 18 months, in 1 life was prolonged 1 year, 1 is markedly improved at the end of 11 months, 1 received no benefit, 1 had a pelvic metastasis at the end of 8 months, but was improved just after the operation, and 1 was greatly improved at the end of 4 months, when she died of intestinal obstruction. [F. T. S.]

10.—Rankin details the history of a man aged 72 who developed **senile gangrene** from an ingrowing toe-nail on the right side. The disease to the adjoining toe and the foot became considerably swollen. The limb was disarticulated at the knee joint and an uneventful recovery followed.

[F. T. S.]

11.—Morison gives a table of 20 consecutive cases of **pyloroplasty** showing the results at periods varying from six years and eight months to 2 years after operation. He thinks the procedure is one of the most satisfactory operations in abdominal surgery. Fourteen of the patients are in good health, 1 could not be found, but was in good health when last heard of, 2 are dead, and 3 are much improved, but still have occasional stomach troubles. Of the deaths 1 occurred 6 months after the operation from cancer, a malignant

being mistaken for a fibrous stricture, and the second died 2 years and 3 months after pyloroplasty; until the commencement of his last illness he was perfectly well.

[F. T. S.]

12.—Marsh lays down the precautions to be taken in advising massage and discusses its physiology. Massage and exercises are indicated in **sprains and contusions** of previously healthy joints in which there is no fracture, subluxation, displacement of tendons, or pre-existent affection as tuberculosis, gout or hemophilia. The after treatment of dislocations has undergone a most advantageous change. After a dislocation of the shoulder the arm is now kept in a sling for a day or two until the pain has subsided, then daily passive motions and massage are begun. Concerning the remote treatment of injured joints it is of great importance to eliminate tuberculosis, rheumatism, gout, sarcoma, and hemorrhagic effusion into the joint due to hemophilia, before motions are begun. Stiffness and pain are the chief indications for the movement of an articulation. These are due to some condition outside the joint, even if a limited amount of normal smooth motion is retained. Muscle wasting is invariably present when the joint is involved and it may be present, though never extreme, when the periarticular structures alone are injured. In those patients whose joints are slightly swollen and a little stiff for a prolonged period after an injury, the symptoms are probably due to a slender adhesion which may be broken under an anesthetic. Whitlock called attention to the value of the salicylates in injuries of the joints in the rheumatic. Burghard advocates daily massage with careful and gradual movement under gas once a week for adhesions following dislocations. Cousins said that too much rest is commonly employed; that after breaking up a partial ankylosis splints and bandages should be discarded and that the joint should be put into immediate use. Barling discards splints in Colles's fracture unless the deformity is great; he commences passive motion 2 days after the injury. Morison thought that a certain amount of rest was essential following joint trauma. [F. T. S.]

13.—Burghard thinks that **congenital dislocation of the hip**, when seen under the second year, should be treated by massage, passive movements in the direction of extension and abduction, and weight extension to the limb at night. Between 2 and 5 years, the Lorenz method should be tried. The surgeon should not be satisfied until the head of the bone is in place. If an X-ray examination shows that the dislocation has not completely reduced, the manipulation may be repeated two or three times at short intervals. If it then fail, the open method is to be employed without further waste of time. When seen in the sixth or seventh year, the open method is indicated unless a single trial of the Lorenz method shows that the bloodless reposition is likely to succeed. After the age of 7 an apparatus modelled upon the Shede's should be worn to diminish the unsightly waddle.

[F. T. S.]

14.—Dunbar narrates a case of partial dislocation of the head of the femur downwards and outwards which was reduced 5 years after the original injury; and a case of subluxation of the right ilium forward, which was reduced 6 years after its occurrence. [F. T. S.]

15.—Whitlock reports the case of a woman aged 28 on whom he operated for what was supposed to be an empyema of the right pleura. A swelling about the size of an orange was seen over posterior portion of the eighth intercostal space; portions of the ribs just above and below this were resected evacuating a straw colored fluid containing many small cysts. An unsuccessful effort was made to remove the mother cyst, about 5 months later it appeared in the wound and was extracted with forceps. The patient is now in good health. The source of infection could not be determined; the woman had always resided in England.

[F. T. S.]

17.—This patient was a woman aged 27 years who had suffered with pain in the back since childhood. She presented a left-sided abdominal cyst which was diagnosed as a hydronephrosis. The left kidney was exposed through an incision in the loin and found to be normal. A second incision through the left semilunar line disclosed a **multilocular cystoma of the pancreas**. This was dissected from its bed up as far as the head of the pancreas, and there amputated after passing interlocking sutures of silk

through the organ. On the tenth day following operation, all the stitches having been removed, the wound burst open, allowing the intestines to prolapse. They were washed, replaced, and the wound resutured. Uneventful recovery ensued. The patient's appetite and digestive powers were and still remain good; neither before nor after the operation was any excess of undigested fat found in the stools; and the urine has never exhibited even a trace of sugar.

[F. T. S.]

LANCET.

October 19, 1901.

1. Introductory Address. OLIVER LODGE.
2. A Clinical Lecture on Tumors of the Parotid Gland. H. T. BUTLIN.
3. Developmental (Myelogenetic) Localization of the Cerebral Cortex in the Human Subject. PAUL FLECHSIG.
4. On the Protective Substances of Immune Sera. E. W. AINLEY WALKER.
5. Gynecological Cases. G. MACNAUGHTON-JONES.
6. The Prevention of Asphyxia When the Birth of the After-coming Head is Delayed. G. F. BLACKER.
7. The Treatment of Hemiplegia. LEONARD G. GUTHRIE.
8. The Treatment of Syphilis, etc. WINFIELD AYERS.

2.—Butlin, in a clinical lecture on tumors of the parotid gland calls attention to the difficulty in differentiating malignant from benign growths of this gland. A few years ago many cases of malignant growth were reported which did not recur after removal, and it seemed at that time that the prognosis of malignant growths of the parotid gland was more favorable than of those situated elsewhere. It has since been shown, however, that many of the tumors supposed to be sarcomata were really endotheliomata. Some pathologists deny the occurrence of sarcoma of the parotid gland. The lecture is illustrated by the presentation of a number of patients who had been operated upon. The improvement in the surgery of the parotid gland must lie in earlier recognition of the nature of the disease affecting it. [J. H. G.]

3.—Flechsig gives an outline of the developmental (Myelogenetic) localization of the cerebral cortex in the human subject. A part of the author's researches which have been carried out some time ago, and new researches on the human subject, lead to the conclusions that the convolutions are divided at certain periods of age into regions which are, "1st, well provided with medullary substance, 2nd, scantily provided with medullary substance, and 3rd, altogether devoid of medullary substance." He has estimated the number of myelogenetic cortical areas at 36 and he states that a special anatomical position, and therefore also a special functional importance is attached to each area of myelogenetic localization of the cortex. These cortical centers, he also classifies into three groups: "1st. Regions of early development (primordial zones); 2nd. Regions of the intermediate development (intermediary zones). 3rd. Regions of late development (terminal zones). The author then discusses the significance of each zone.

[F. J. K.]

4.—Walker in a preliminary communication writes on "the protective substances of immune sera." The minimum lethal dose of a given bacterial culture being known, and the dose of immune serum sufficient to protect against the dose of the toxine, this is designated as its serum equivalent. It has been shown that if an animal be given two minimum lethal doses of the bacterial culture and two doses of the serum equivalent, infection and death follow, the animal therefore is not protected. He states that this is explained on the ground that there exists a deficiency in the leukocytic ferment in the animal concerned, but in reality, the amount of immune body given in the immune serum is deficient. From his experiments he deduces the following: That the leukocytic ferment of different animals would supply the lactic ferment of some other animals, and further that addiment is not so special to the species as claimed by Professor Ehrlich. He reaches the following conclusions: 1st. Addiment is not extremely

special to the species. 2nd. Addiment is a leukocytic ferment. 3rd. Addiment is increased during and by immunization. 4th. The immune body is produced exclusively by the leukocytes. 5th. Agglutinations assist the phagocytic process." [F. J. K.]

5.—Macnaughton-Jones reports a series of gynecological cases including a primary tuberculosis of the Fallopian tube associated with pyosalpinx in a young woman of 22 years, also a large hernia following an abdominal section, the hernial sac protruding over the pubis and covered only by integument. A surgical operation with tier-suturing resulted in a cure. Also, a large fibromyoma removed by hysterectomy with recovery of the patient. The tumor weighed 28 pounds. [W. A. N. D.]

6.—Blacker gives a historical note upon the methods for the prevention of asphyxia, when the birth of the after-coming head is delayed. He refers to the obstetrical authorities from 1754 to date who have treated of this subject, including a description of Pugh's method, which consisted in the introduction of a tube made of metal, spiral wire, or elastic gum, such a tube acting as a prolongation of the trachea. Barnes, in his book, mentions that he kept a child alive for 10 minutes in a case of breech-presentation by retracting the perineum, thereby enabling air to enter the chest. The author remarks that the passage of a catheter or special tube into the child's mouth, when the head is lying high up in the pelvic cavity, is likely to lead to a waste of valuable time, while if the head is sufficiently low down in the pelvis to admit of air reaching the mouth, if the perineum be retracted, its immediate extraction should be a matter of little difficulty. [W. A. N. D.]

7.—Guthrie discusses the treatment of hemiplegia. The author emphasizes that the treatment of hemiplegia is usually limited to the administration of iodide of potassium, strychnine, and other drugs, and attention to hygienic surroundings, but the treatment of paralysis is almost constantly neglected. He also emphasizes that mild cases never recover unless treated, and severe cases go from bad to worse unless treated vigorously. This paper mainly deals with the treatment of paralysis, which is due partly to articular adhesions, partly to the motor paralysis leading to muscular atrophy, and in part to spasticity or spasmotic contraction, which finally induces shortening of the stronger muscles. Paralysis when treated early would lessen the number of incurable patients, and would alleviate the number of incurable ones, but when the conditions just named are in a far advanced state, they are hopeless. He summarizes as follows: "1. Neglect and want of treatment aggravate severe, and retard the recovery of mild cases. 2. The evils to be foreseen and guarded against are articular adhesions, late rigidity, and muscular atrophy. 3. Articular adhesions should be prevented by passive movements of each joint from the very first. 4. Faulty positions of the limbs should be constantly corrected or they will become chronic. 5. Contraction of the muscles should be treated by endeavors to improve the nutrition of their weaker opponents. 6. Massage, passive movements, and, to a less extent electricity, should be used with this object. These agents not only counteract muscular atrophy from disuse, but probably take the place of normal stimuli and invigorate the neurons. 7. The recovery of mild cases may often be hastened by re-education of the movements. Want of re-education often prevents recovery. 8. Re-education consists in a combination of passive and active exercises. 9. Movements should first be encouraged in those parts which naturally tend to recover first. 10. Incoordination and general weakness of the limbs, which have not yet regained power of movement, should be treated by exercises and mechanical therapeutics. 11. It is important to find out what the patient can do and make him do it."

[F. J. K.]

8.—Ayers discusses the treatment for syphilis with special reference to the best method of administering mercury. As the result of an extensive experience based on 180 cases treated with mercuriol, he finds that this preparation given in tabloids, one grain doses, steadily increasing the dose until slight tendency on the part of the gum and teeth to become tender, is the best method of administering mercury. [F. J. K.]

MEDICAL RECORD.

November 2, 1910.

1. Carbonate of Creosote as a Remedy for Pneumonia, etc. LEONARD WEBER.
2. On the Use of A. C. E. Mixture and Ethyl Bromide in Operations for Adenoid Vegetations. J. G. GLEITSMANN.
3. Notes on Vienna Hospitals. JOHN E. SOMERS.
4. The Pathology of Bright's Disease. GEORGE E. DAVIS.
5. A Report of Some Cases Presenting Gross Lesions of the Basal Ganglia. M. L. PERRY.

1.—Weber reports nine cases of pneumonia that were treated by carbonate of creosote in doses of from 40 to 60 grains daily. Eight of the patients recovered and one died of myocarditis during convalescence. [J. M. S.]

4.—Davis believes that in the pathogenesis of dropsy, albuminuria, by withholding nourishment, produces (1) an alteration in the composition of the blood, or anemia and hydremia; (2) an alteration in the texture of the capillaries; (3) an alteration in the condition of the vasomotor nerves which control the circulation, the exudation, and the absorption by the capillaries. Uremia is a mixed form of poisoning, due to many causes, and we cannot offer one explanation alone for all accidents of bad repute which may appear in the course of Bright's disease. [J. M. S.]

5.—From a study of three cases, Perry concludes that (1) the corpus striatum has no intimate relation with either the motor or the psychical centers; (2) that there may be a very extensive lesion involving both the caudate and the lenticular nuclei without giving rise to symptoms; (3) that there is in the posterior portion of the lateral nucleus of the thalamus an area, irritation of which will produce immediate loss of consciousness with convulsive movements upon the opposite side, and destruction of which will produce immediate death; (4) that there may be a tumor of considerable size involving the pineal body without giving any pressure symptoms; (5) that the pineal body may be entirely destroyed by disease without producing symptoms; (6) that there is no tract of nerve fibers originating in the pineal gland and connecting it with the remainder of the brain. [J. M. S.]

MEDICAL NEWS.

November 2, 1910. (Vol. LXXIX, No. 18).

1. Some Observations on Southern California. SAMUEL A. FISKE.
2. Examination of the Mouth in Infancy and Childhood. JACOB SOBEL.
3. A Case of Concussion of the Brain and Hystero-Epilepsy. WILLIAM B. NOYES.
4. On Experimental Tuberculosis of the Suprarenal Capsule in Relation to Addison's Disease. Preliminary Report of a Pathological Study. RINDO De VECCHI.
5. The Physician as a Social Factor. ALEXANDER ROVINSKY.
6. An Interesting Accident of Staining. J. O. COBB.

2.—J. Sobel says that for a thorough inspection of the mouth of infants and children, three conditions are necessary: (1) Good position; (2) good light; (3) good tongue depressor. He advises the use of Chapin's tongue depressor, particularly when a very thorough inspection of the pharynx and tonsils is desired. Inspection of the anterior surface of the epiglottis is frequently a simple matter with this depressor, especially in very young children. He also gives the following method for a systematic examination of the mouth: The depressor is inserted at the left angle of the mouth, the cheek and lips everted, then at the right angle, and the cheek and lips everted. The spatula then catches the frenum, and the under surface of the tongue, the frenum and the floor of the mouth are observed; the spatula being removed, the upper surface of the tongue is viewed; the latter is then firmly depressed and the hard and soft palates, fauces, tonsils, pharynx, and in the vast majority of cases the epiglottis are observed. [T. M. T.]

3.—W. B. Noyes in his article on Concussion and Hys-

tero-Epilepsy states that hystero-epilepsy may mean general hysteria with hysterical convulsions, or definite epilepsy with intercurrent epilepsy, or it may be a convenient term to cover up one's ignorance as to whether hysteria or epilepsy is the proper diagnosis. From a legal standpoint this is not an unimportant question, for, in the minds of the majority of lawyers as well as jurymen, hysteria is still held to be synonymous with simulation. To establish a pathology for such combined cases during life and frequently by autopsy is a difficult problem. Admitting the presence of an exhaustion paralysis of a temporary nature following an epileptic fit, and also admitting that the condition present in a case of temporary hemiplegia which the author reported, and in a long series of cases reported by Clarke of the Craig Colony of various other paralyzes, is truly the result of exhaustion, the question arises, why are not these complicated symptoms, which we call hysteria, so closely associated with definite epileptic attacks, to be explained also as fatigue symptoms in a man who was originally suffering from concussion of the brain, and secondarily from epilepsy? One condition is common to all these traumatic cases, and that is, whether or not litigation is being carried on, they have almost lost the power of working continuously at any occupation, and fatigue promptly follows any exertion. [T. M. T.]

4.—B. De Vecchi, in his report of experiments on the above conditions, says it is clear that by tuberculizing the suprarenals a serious poisoning of rabbits is produced which ultimately leads to their death. The circulating poison has great destructive properties, as is shown by the pathological changes in the heart, liver and kidneys, and the cells of the central nervous system are particularly vulnerable. These injuries explain the nervous symptoms of those suffering from Addison's disease. He did not observe any secondary changes in the sympathetic cells and in the rabbit where the celiac ganglion was partially destroyed; he encountered no symptoms not seen in the other animals. Although he says he has certainly succeeded in causing an intoxication in animals by this special method, he has been unable to reproduce the characteristic bronzed skin. He also states that the cause of the diseased condition produced lies in the gradual destruction of suprarenal substance. To this undoubted capsular insufficiency must, however, be added the tuberculous intoxication, so that we have two factors to deal with. The author believes that he has reproduced as nearly as possible the process as it goes on in the human body, and while he does not believe he has entirely settled the question, it has been brought nearer to solution and an entirely new method of research has been opened. [T. M. T.]

6.—J. O. Cobb found in staining for tubercle bacillus with methyl instead of methyl blue a rod about three times the size of the tubercle and shaded light lilac. In studying this rod it was found to be a crystal of the stain. It was also noticed that the presence of carbolic acid and heat produced beautiful crystallization, and fresh preparations of the stain gave crystals much more uniform in size and much smaller than in old preparations. The author also calls attention to the accident of staining with Sudan III and does not advise its use on account of the deposit of crystals resembling closely the bacillus. [T. M. T.]

THE NEW YORK MEDICAL JOURNAL.

November 2, 1901. (Vol. LXXIV, No. 18).

1. Address in Surgery. REGINALD H. SAYRE.
2. The Lane Lectures on the Social Aspects of Dermatology. MALCOLM MORRIS.
3. Scientific Aids to Diagnosis. HENRY H. HOLTON.

1.—R. H. Sayre, in his address on surgery, gives Cabot's blood experiences in over a hundred cases of appendicitis: (1) Red cells: No change occurs save in old chronic abscess; (2) Coagulation is slow, but fibrin is increased; (3) As in most infections, the mildest and the severest cases show no leukocytosis; this absence in a case which is distinctly serious is as bad a prognostic as in pneumonia or diphtheria; (4) Catarrhal appendicitis is really accompanied by leukocytosis; (5) An increasing leukocytosis is equivalent to a spreading process and may be the sole

evidence of this fact; a steady increase is a very bad sign and is more important than a large count that does not increase; (6) After walling off, the count remains stationary or decreases. [T. M. T.]

3.—H. H. Holton states that all cases demanding operative intervention, except emergency cases, should not be operated upon until the result of the blood examination is known. He gives some blood examinations as follows:

Normal Blood.

Quantitative—

Red Cells	4,500,000—5,500,000
White Cells	6,000—10,000
Blood Plates	200,000—300,000
Hemoglobin	100—90 degrees (Fleischl)

Qualitative—

Red cells, uniform size and shape. No nucleated cells in adult blood.

White cells—

Young,	
Large lymphocytes	20-30 per cent.
Small lymphocytes	4-8 " "
Adult (polymorphonuclear neutrophils)	62-70 " "
Old (eosinophiles)	1½-4 " "
Mast cells	¼-½ " "

Primary Anemias.

Chlorosis.

General.—Blood as a whole very pale in marked cases, coagulates rapidly. Fibrin not increased. Specific gravity low.

Quantitative—

Red cells, 4,000,000.
White cells normal.
Hemoglobin, 25 to 60 degrees.

Qualitative—

Red cells, small, pale, often deformed. Nucleated corpuscles rare.
White cells, increase in lymphocytes.
Blood plates, increased.

Pernicious Anemia.

General.—Blood excessively pale, watery, and fluid; coagulates slowly. Uneven, streaky appearance of drop.

Quantitative—

Red cells, 1,500,000 to 1,000,000 or less.
White cells, 4,200, to 500.
Hemoglobin, 60 to 20 degrees (usually high in proportion to number of cells).

Qualitative—

Red cells, increase in average size. Deformity of shape (poikilocytosis). Staining changes. Nucleated corpuscles present: Megaloblasts (most numerous); normoblasts.
White cells, large percentage of lymphocytes; small percentage of myelocytes.

Leukemia.

General.—The drop as it emerges from puncture looks perfectly natural, very sluggish, coagulation slow.

Splenic Myelogenous Form.

Quantitative—

Red cells, about 3,000,000.
White cells, about 450,000.
Hemoglobin, 30 degrees.

Qualitative—

Red cells, nucleated forms numerous.
White cells, 30 per cent. myelocytes.

Lymphatic Form.

Quantitative—

Red cells, 3,000,000 or lower.
White cells, 100,000 or lower.
Hemoglobin, 30 degrees.

Qualitative—

Red cells, nucleated forms rare.
White cells, 90 per cent. lymphocytes.

Typhoid Fever.

General.—The blood appears normal on puncture. Coagulation and fibrin are normal.

Quantitative—

Red cells, 4,000,000 to 1,300,000; in the third week begin to decrease.

White cells, no increase; in late weeks decrease.

Hemoglobin, loss relatively greater than loss of cells.

Qualitative—

White, increase in proportion of young leukocytes.

Serum, agglutinin appears on the average in from 5 to 8 days.

Malaria.

General.—The presence of the plasmodium malarie is absolute proof of this disease.

Quantitative—

Red cells, 2,000,000 to 1,000,000. Reduced in number after each paroxysm. A tendency toward regeneration and restitution during the afebrile periods.

White cells, numbers subnormal, decreasing during paroxysms and rising toward normal again during the afebrile period.

Hemoglobin, diminished with red cells.

Qualitative—

Red cells, deformity in size and shape. Normoblasts, megoblasts, and ghost cells (resembling pernicious anemia).

White cells, lymphocytosis. Increase in eosinophiles.

Septicemia.

General.—Blood in macroscopic appearance normal. The infecting organism can usually be separated by cultural methods.

Quantitative—

Red cells, 3,000,000 to 1,000,000; diminution depending on severity of disease.

White cells, marked increase in majority of cases.

Hemoglobin, running parallel with red cells, often exuding and staining serum.

Qualitative—

Red cells, very little deformity.

White cells, polymorphonuclear variety most in evidence.

In conclusion the author would impress upon the rural practitioners, who make up the great bulk of the profession, the great possibilities that these various aids present to them, if they only choose to avail themselves of, and perfect themselves in, the use of these advances in scientific accuracy. [T. M. T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

October 31, 1901.

1. The Mechanics of Lateral Curvature as Applied to the Treatment of Severe Cases.

ROBERT W. LOVETT.

2. Intermittent Hydrops. E. G. BRACKETT.

3. Association of Anemia With Chronic Enlargement of the Spleen. ARTHUR H. WENTWORTH.

4. A Case of Anomia and Paraphasia.

GEORGE H. THOMAS.

5. On the Passing of the Trephine.

THOMAS H. MANLEY.

1.—In cases of scoliosis with fixed bony curves, the same theory of corrective treatment cannot be applied as in cases of scoliosis with flexible curves. The fact that there is a fixed portion of the spine situated between two movable parts makes it easier to twist or displace the thorax as a whole than to make any change in the curved portion itself. As a result of this, forcible attempts to correct bony rotation in fixed curves will increase the lateral curve, unless the thorax is kept from rotating, and forcible attempts to correct the lateral curve are likely to increase the rotation. To judge from the observations on the cadaver, suspension as a corrective agent has but little corrective effect in rigid cases. For the application of forcible jackets, the prone position, with the legs hanging perpendicularly, seems the most effective. Forcible correction seems to have its place only as preliminary to gymnastic treatment. [J. M. S.]

2.—Intermittent hydrops is an affection without discoverable anatomical basis, without proof of infection, giving a simple, noninflammatory, serous effusion in the joints, occurring at regular inexplicable periods, interrupted without rule, or in accordance with what may be termed psychic stimuli, associated in some instances with what are usually classed as functional nervous disorders. Certainly,

the disease seems to be a functional, as opposed to an organic, trouble; and whether we do or do not call it a vasomotor trouble or a neurosis, depends largely on our reluctance towards these catch-alls for unexplained disorders. [J. M. S.]

3.—In infancy and early childhood there is a severe grade of anemia associated with marked enlargement of the spleen, the etiology of which has caused a great deal of discussion. The disease, known as anemia infantum pseudoleukemica was believed at one time to be a primary disease of the blood. Its prototype, in the adult, anemia splenica, was thought to be a primary disease of the spleen. The author believes that they are secondary conditions dependent upon a number of causes. After an exhaustive résumé of the literature on the subject, the author makes the following summary: (1) The blood changes of so-called anemia splenica are those of a secondary anemia. (2) The degree of cachexia, that has been described in these cases, does not always correspond to the blood changes. It is not improbable that the cachexia and other symptoms are produced by a chronic intoxication similar to that produced by carcinoma, tuberculosis, etc., and that the splenic and blood changes are merely two of the results that are thus produced. The source of the intoxication is unknown, and it is very probable that it may come from various sources. (3) The mere interference of function from an overgrowth of connective tissue in the spleen could not produce the symptoms described as characteristic of anemia splenica. (4) If it were possible for fibrous tissue to produce toxic substances, it is difficult to account for the absence of such substances in connection with chronic hyperplasia of the spleen when associated with a variety of well-known causes. (5) It has been stated that the splenic alterations are primary, and precede all of the other symptoms. This statement requires further observation to confirm it. The lesions in the spleen are characteristic of chronic hyperplasia, a condition which is associated with a number of abnormal conditions in various organs, and which frequently gives rise to no symptoms, or in other cases causes such symptoms as may be produced by the size and weight of the organ. (6) The lesions found in the spleen in cases of so-called splenic anemia do not warrant the statement that this condition is related in any way to pseudoleukemia. There is no analogy between the hard glandular form of malignant lymphoma and the lesions of chronic hyperplasia in the spleen. (7) A tendency to generalize from observations made upon 1 or 2 cases is to be deplored. In the case of splenic anemia nothing characteristic of a primary disease has been discovered in any organ or in the blood. (8) The evidence is conclusive that anemia infantum pseudoleukemica are objectionable, because they are it owes its peculiar symptoms and blood changes to the occurrence of severe anemia at an early age. (9) There is little doubt that anemia infantum pseudoleukemica and anemia splenica infettiva are identical conditions, and there is even less proof that anemia splenica infettiva is a primary disease of the spleen than that anemia infantum pseudoleukemica is a primary disease of the blood. (10) There is no apparent connection between the character of the blood and the splenic changes in infancy. (11) All that one is justified in concluding about these secondary anemias of infancy is that in some cases there occurs a chronic hyperplasia of the spleen, and in others the spleen is not altered. (12) The names anemia splenica, primary splenomegaly, anemia splenica infettiva and anemia infantum pseudoleukemica are objectionable, because they are misleading. [J. M. S.]

4.—Thomas reports a case of a lawyer, 60 years of age, who was suffering from a discharge from his left ear, of 20 years' duration. With this exception he had always regarded himself as perfectly well. A few months previous to the occurrence of his present illness, the patient had headaches for the first time in his life; and about 5 months before the symptoms developed, he acted very strangely to his wife, using profane language to her; an occurrence which he afterwards entirely forgot. About 5 weeks before he was seen by the author, the patient began to have intermittent attacks of headache. These headaches became more severe, and were more or less persistent day and night, and, finally, were so troublesome that he was compelled to consult his family physician. Then it was found that the patient had a noticeable difficulty in finding

words to express himself. One thing especially noticed was that on entering into the office he went to the stove, in which a hot fire was burning, and stretching out his hands, asked if there was a fire in the stove. This question was repeated several times by the patient, although the doctor each time gave an affirmative answer. At this time he was able to make out legal documents of complicated nature which were found to be carefully written in every way. The patient's breath was exceedingly offensive; his tongue was dry and heavily coated; the pulse was 90 and weak; the temperature was normal; and the pupils reacted to light. When shown any object and asked to name it, he found it impossible to do so, though he apparently recognized perfectly what the object was, and frequently indicated his knowledge by trying to show its use. Pressure over the left side of the skull revealed a point of great tenderness, about 3 inches above the tip of the mastoid; and deep pressure here provoked almost unbearable pain, which lasted 5 or ten minutes. There was no tenderness anywhere else on the skull. Besides this anomia, the patient was unable in many instances to apply fitting adjectives. The lesion which produced these symptoms was believed to be located in the left temporal lobe, below the angular gyrus. The skull was trephined over the superior temporal lobe and over the left lateral lobe of the cerebellum, with negative results. The patient died on the following day. At the post-mortem, the mastoid antrum and cells were found filled with foul-smelling, inspissated pus, and the bone was necrosed. There was an abscess cavity in the posterior part of the lower left temporal convolution. The abscess was about the size of a walnut, and it was filled with thick, foul-smelling pus of gelatinous consistency. Extending around this area, for a distance of about $\frac{3}{4}$ of an inch in all directions, the brain tissue was found softer than elsewhere. [J. M. S.]

5.—In vault fractures make a large incision to expose the skull freely. Leave all aseptic sub- or epidural coagula, however extensive, undisturbed. All lacerations in the dura mater should be securely closed with fine aseptic gut suture. Reimplantations of trephine buttons of skull bone have invariably failed, and any procedure which will conserve the skull is of great advantage to the adult. In a child under 15 years, as Ollier has correctly demonstrated, the periosteal layer of the dura mater will regenerate ample new osseous tissue to fill a large breach. Silk-worm gut, or *Crin de Florence* fish gut, answers best for suture of the scalp; small wicks of aseptic gauze in the angles of the wound provide for ample drainage. For antiseptic powder over the wound nothing surpasses finely ground fresh mustard. Mauley uses the osteotome instead of the trephine. [J. M. S.]

10. The Treatment of Typhoid Fever in Children. HENRY E. TULEY.

1.—Fuller points out the great mortality, direct and indirect, of prostatic hypertrophy and regrets the apathy of the community and the medical profession concerning the operative treatment of this condition. A man under 65 is young from the standpoint of prostatic surgery. The majority of the cases are best treated by prostatectomy; they may be grouped as follows: (1) Those not amenable to urethral instrumentation; (2) those demanding vesicle or

perineal drainage as well as relief from prostatic obstruction; (3) those in which renal infection exists; (4) those complicated by phosphatic calculi in which litholapaxy is impracticable; (5) those in which the prostatic mass is not amenable to less radical surgery. Most of the cases of castration which he has seen were not relieved but subsequently submitted to prostatectomy. The Bottini operation is not a radical cure, residual urine almost always remains; it fails to relieve in a good percentage of the cases and the mortality is in the neighborhood of 10%. "If an individual is quite elderly, say around 75 or over, and is suffering from obstruction due to a middle lobe of not great size, it might be, in the absence of contraindicating complications, that the Bottini operation would then be the one of choice." One reason for the fleeting good results after the Bottini operation is the contraction which attends cicatrization following the burning. Fuller states that the mortality of prostatectomy is not over 8 or 10% in individuals not over 65 and who are otherwise healthy.

[F. T. S.]

2.—Syme says the Bottini operation does not appeal to him as a sound surgical procedure. It does not remove the prostate and only partially relieves the obstruction in most cases. The slough must separate and pass through the urethra leaving a burned wound in the presence of infected urine. Prostatectomy will be the favorite operation in the future, if it can be made reasonably safe. The author makes a median incision in the perineum, opens the membranous urethra and through this opening inserts what he calls a "bladder retractor." It consists of a soft rubber tube to the end of which is cemented a rubber bulb. When the bulb is distended with water it measures about 2½ inches in diameter; by pulling on the tube the bladder is brought within satisfactory reach. The capsule of the prostate is perforated and each lobe enucleated separately. The retractor is emptied, withdrawn, and a large drainage tube introduced through the perineum into the bladder. Syme has operated on nine cases ranging in age from 53 to 75 years. All but one had cystitis, two had stone, and the residual urine varied from 3 to 5 ounces. All of the patients have lived and all but one, who was only partially relieved, because the entire gland was not enucleated, are completely cured. [F. T. S.]

3.—Guitarras reviews the various methods of prostatotomy and of prostatectomy, and compares the results of each. Of 753 prostatotomies, 622 were cured, 44 died and 87 were failures; or 82.5% cured, 5.8% died, and 11.5% failures. Of 152 prostatectomies, 110 recovered, 25 died, and 17 were failures; or 72.3% cured, 16.4% died, and 11.2% failures. The results in those that recover from prostatectomy are better and more permanent than those following prostatotomy. The operation to be preferred will be decided according to the age of the patient, the size of the prostate, and the condition of the bladder and kidneys. In very old men if the prostate be of the right variety the Bottini method should be performed. Large glands are favorable for enucleation while small ones are best treated by prostatotomy. If the kidneys be diseased either medically or surgically, the Bottini operation is indicated.

[F. T. S.]

4.—L. L. McArthur has been conducting some experiments upon animals and human beings in the use of the aponeurosis of the external oblique muscle as a suture material for the purpose of closing the inguinal canal in the radical cure of hernia. It is his custom to separate a small portion of the fascia about ¼ to ½ of an inch wide from the internal pillar, excepting at its pubic attachment. A piece of silk with a needle attached is then fastened to the free end. Although flat when first cut, this portion of fascia soon assumes a round shape and can readily be drawn through the tissues by means of the needle and thread attached to its free extremity. Where two layers of sutures are required, as in the Bassini operation, two strips of fascia may be separated, one from the internal and the other from the external pillar. The author had employed this method of suturing in twenty cases of inguinal hernia with perfect primary union in all. The advantages claimed for the method are: (1) "The obtaining of a living suture; (2) lessened chances of failure through avoidance of introduction of dead or foreign tissue; (3) The incorporation in the resisting cicatrix of organized white fibrous tissue; (4) the applicability of the same procedure to other

situations." By his experiments upon dogs McArthur has shown that the tissue is not absorbed, does not slough, but heals *in situ*. In very young children and in some women the external oblique is occasionally so poorly developed that the application of the author's method is unpracticable. The tensile strength of the strips of tendon is sufficient to stand a strain of from 11 to 24 pounds. Sufficient time has not elapsed since the author's operations to render his report final. [J. H. G.]

5.—See Philadelphia Medical Journal, June 15, 1901, page 1139.

7.—J. H. Carstens, in discussing the requirements of modern surgery, refers to the progress surgery has made during recent years and its present requirements. His conclusions are as follows: "(1) A patient brought to the highest state of resistance to microbial infection and made as clean as possible. (2) An operating-room, preferably in a hospital, where everything has been made thoroughly sterile. This includes anesthetizer, assistants and nurse. (3) A surgeon who has a mechanical hand and has received a long, thorough training." J. H. G.]

8.—Evans reports four cases of fat necrosis in connection with gallstones. The first occurred in a woman 45 years of age, who had had attacks of biliary colic for eight years. Only one of these attacks of gallstone colic was associated with jaundice. After the last attack of biliary colic, symptoms of localized peritonitis developed. The patient was operated upon and 250 stones were removed from the gallbladder. The common bile-duct was unobstructed. Yellowish white nodules were found in the omentum. The patient died 36 hours after the operation. At the time of the operation two of these soft yellowish white nodules were excised from microscopical examination. The second case occurred in a man between 30 and 40. Attacks of gallstone colic accompanied by occasional jaundice had occurred during the past three years. During the six weeks preceding the operation which was done for the relief of the gallstones, he had been ailing and his general health was much impaired. During this time jaundice was marked and the gallbladder appeared distended and tense. Death soon followed the operation. A post-mortem examination was made two hours after death, and it was found that the great omentum which was glued to the anterior abdominal wall was the seat of extensive fat necrosis. The mesenteric fat and the perirenal fat were also involved by fat necrosis. The pancreas was in a state of hemorrhagic inflammation. The third case occurred in a man, 59 years of age, who had been ailing for ten days, complaining of jaundice, swelling of the abdomen, and diarrhea. Considerable tenderness existed over the liver. It was ascertained that three previous attacks had occurred during the past five years. Death occurred on or about the fifteenth day of the illness. At autopsy it was found that the peritoneal cavity contained a large quantity of bloody serous fluid and the parietal peritoneum was the seat of petechial hemorrhages. The liver weighed 2960 grams. The surface was irregular, granular, and the common duct was patulous. In the pancreas and around this organ areas of fat necrosis were present. The fourth case occurred in a married woman who had given birth to a healthy child early in May, 1901. On June 20th, abdominal pain developed. Subsequent attacks of abdominal pains occurred which were attended with slight jaundice. A calculus about the size of a half split pea was found in the stools on June 21st. On July 28th, a second calculus was passed. At the operation which was performed on August 3rd, the gallbladder was opened and the appendix was explored. A number of stones were removed from the gallbladder. The common bile-duct was patulous. The peritoneum was studded with numerous white paper like dots and lumps, some of these were removed for microscopical examination. The author next discusses the anatomy of the pancreas and biliary ducts. In referring to the diagnosis of fat necrosis, he emphasizes that pain in fat necrosis is generally located in regions other than that of the gall bladder. Occasionally the pain which attends fat necrosis remains localized to a particular area, but more frequently it is of a shifting character and is difficult to locate. At other times the pain is slight and amounts to only a sensation of discomfort which is most pronounced in the epigastric region though spreading to other parts. Gallstones accompanied

with fat necrosis are as a rule attended with fever. It should be born in mind that, after an attack of biliary colic, general abdominal soreness is present and if this persists it should suggest fat necrosis. [F. J. K.]

9.—Carl Beck reports a case of **fat necrosis associated with gallstones**. The patient was a woman 26 years of age. She had a number of typical attacks of gallstone colic and passed portions of gallstones in her stools. Just before she was operated upon she suffered for several days from a shifting pain in the abdomen. At one time it was present in the appendix region and later it was most marked in the neighborhood of the spleen. At the operation the omentum, the peritoneal coat of the intestines, and the mesentery were found studded with areas of white spots ranging in size from a pin head to five mm. in diameter. These areas were not round like tubercles, but angular, flat and somewhat depressed. The condition closely resembled tubercular peritonitis, but a microscopic examination showed the condition to be one of fat necrosis. The gallbladder was opened, and from it were removed a number of gallstones varying in size. The bile ducts were found free of any obstruction. After operation the patient was fed entirely by the bowel for nine days, and to this treatment Beck attributes the satisfactory recovery which followed. Attention is called to the frequent association of gallstones and fat necrosis. [J. H. G.]

10.—Tuley gives an outline of the **treatment of typhoid fever in children**. He states that the dietetic treatment is a most important division and he believes that milk, kumyss, buttermilk, broths, and concentrated liquid foods are most suitable. Free indulgence in water should be encouraged. The author is an advocate of the tub or sponge bath, or the application of cold in the form of a wet pack. He has found that cold colonic flushing frequently reduces the temperature. He states that on more than one occasion he has used no internal medication whatever, depending entirely upon hydrotherapeutic measures. He recommends bismuth subnitrate, and tannalbin for the diarrhea, turpentine for the intestinal distension, and strychnia for the weakened heart, and finally he advises that whiskey should be reserved as a stimulant to be used late in the course of the disease, and when administered it should be given with regularity and in considerable size doses. [F. J. K.]

4. Convulsive Tics. OTTO LERCH.
5. The Relative Infrequency of Tuberculosis Among Jews. MAURICE FISHBERG.
6. Should We Burn Our Dead? HENRY D. FULTON.

1.—There is nothing to warrant the assumption that **mental depression** exercises any influence in the causation of carcinoma, except through blood impoverishment which almost invariably exists in melancholia (Steele), a change that appears not to influence the outcome in the male materially, as the percentage of affliction is substantially alike in this sex in all forms of insanity. Hence it appears that the preponderance of **malignant manifestations** in the female should be attributed rather to the broader field of attack than to any form of special vulnerability. [J. M. S.]

2.—The evidence presented in Repp's paper may be summarized as follows: (1) That tuberculosis may be transmitted to animals by feeding them the meat of certain other animals that are tuberculous, or by inoculating them with it. (2) That tuberculosis may be transmitted to animals by the ingestion of the milk of certain cows that are tuberculous, or by inoculating them with it, both when the udder of the cow is diseased and when it is healthy. (3) That, therefore, the meat and milk of certain tuberculous animals contain living, virulent tubercle bacilli. (4) That the tubercle bacilli of cattle are pathogenic for man. (5) That, therefore, the meat and milk of certain tuberculous animals are capable of producing tuberculosis in human beings who use these products as food. It is necessary,

therefore (1) to regard the meat of all food animals, especially cattle, as unfit for food when the animal is highly tuberculous. It may be considered safe as food when the animal is only slightly or moderately tuberculous, especially so if the meat is well cooked and the tuberculous tissues are eliminated. (2) To consider the milk of a cow with a tuberculous udder dangerous for food unless it is well sterilized. The milk of tuberculous cows with healthy udders is also sometimes dangerous for food unless well sterilized. [J. M. S.]

4.—Lerch reports a case of **convulsive tic** in which the patient opened and closed his eyes and rolled the eyeballs. The head was forcibly drawn backward to return with more ease to its natural position. Now and then the movement was so violent that the whole trunk became involved, and was twisted to the right or left. The motions were frequently accompanied by loud, noisy belching, especially morning and night. [J. M. S.]

5.—The external aspect of the **Jew** would lead one to suspect tuberculosis at first sight. His stature is inferior to that of any other European people, and his predominantly narrow girth would give him what is technically known as the "lowest index of vitality." The Jews are also town dwellers. Tailoring appears to be their preferred occupation. A greater proportion of Jews than any other people deal in second-hand clothing, which exposes them to infection by tubercle bacilli. Consanguineous marriages are very frequent among them. These conditions, added to their poverty, constant grief, anxiety, mental exertion, and the ceaseless persecution to which they are subjected, should make them victims to tuberculosis to a greater extent than any other people. But it has long been known to many reliable authorities that the Jews suffer, proportionately, less from the dread disease than any other people. The most plausible explanation of this immunity is the careful selection of the carcasses of food animals in Jewish slaughter houses. Another important factor is the infrequency of alcoholism and syphilis among them. The care that Jews take of their health and the frequency with which they consult physicians, even for slight ailments, have also a great deal to do with their lesser liability to tuberculosis, just as it protects them in times of epidemic ravages from other infectious diseases. [J. M. S.]

6.—Fulton contributes a paper recommending **cremation**. [J. M. S.]

7. The Increase of Elastic Tissue in the Lung in Chronic Passive Congestion. RICHARD MILLS PEARCE.

1.—Simon Flexner contributes a **comparative study of dysenteric bacilli**. The author has made a study of several cultures of bacilli from cases of dysentery. These were made in the usual manner upon culture media, and the reactions toward blood obtained from cases of dysentery and from immunized animals were noted. The dysenteric blood was obtained from immunized cases of Porto Rico dysentery, from Manila, from Presidio and occurring in the Philadelphia Hospital. Of the various sources, gelatine stabs and plates, agar stabs, slants and plates; glucose-agar; potato (parallel); sugar-free bouillon; saccharose, glucose, and lactose bouillon in fermentation tubes; litmus milk, agar colonies, stroke and slant growths, were practically identical. Bouillon was uniformly clouded and a pellicle was not formed. No gas was formed upon any sugar medium; acid was produced, and with little variation in glucose media; litmus milk was at first very slightly acidified, later to become alkaline again. The potato growths showed very slight differences. As to the morpho-

logy of the bacilli, they show only very minor differences; slight variations in length and thickness, due probably to the medium, the growth, temperature and rapidity of the division. As to motility, Flexner's observations show it to be, at best, but feeble. It does not affect all individuals in the field, and is slow and labored. Brownian movement is active. Flagella are possessed by the bacilli. The serum reactions have been of the greatest importance. They indicate close relationship between the bacilli from Japan, Manila, Porto Rico and Germany, and further render probable the identity of the epidemic dysentery of this country with that of the East and Germany. Positive reaction was obtained in dilutions of 1:10 and 1:50 of human blood. Tests with animal blood were positive in greater dilutions, up to 1:200. [T. L. C.]

2.—Simon Flexner and E. M. Pearce present a further contribution to Flexner's paper on **experimental pancreatitis**. They conclude that: 1. Pancreatitis follows upon a variety of insults to the pancreas, and is capable of developing with great rapidity. The introduction of such a foreign body as gastric juice into the pancreas give rise to degeneration, hemorrhage and emigration of leukocytes within the brief space of one to two hours. 2. Chronic inflammations (scleroses) of the pancreas may result from the more remote effects of agents which, acting with greater intensity, produce fatal acute inflammations. 3. Perversion of normal secretions, whereby they enter the pancreas, as illustrated by the effects of gastric juice and bile, are efficient causes of pancreatitis. 4. The presence of blood alone in the tissues of the pancreas does not set up an acute inflammation; the tendency is for the rapid production of a chronic proliferative and inter- and intra-acinar pancreatitis. 5. The effects of blood are not produced by blood-serum separated from the corpuscular elements. 6. The spleen has no influence upon the development of pancreatitis and the production of fat-necrosis. Fat-necroses attend all forms of pancreatitis, and are more numerous and more widespread, the more acutely the pancreatic lesions develop. They may appear as early as eight hours following injury to the pancreas. 8. Glycosuria appears quickly after injury to the pancreas; it may persist for several days and then disappear, although the pancreas has suffered permanent partial injury. [T. L. C.]

3.—W. F. Hendrickson reports a case of **teratoma of the testicle**, showing an extensive perithelial angiosarcomatous growth. The tumor was removed from the patient, who was twenty-five years of age, by Dr. Martin. A histological description of the growth is given with two cuts. The chief point of interest in the tumor was the presence of an anastomosing angiosarcoma with a perithelial proliferation giving rise to gland-like and papillomatous proliferations, associated with connective tissue and cartilage growth, as well as epithelial-lined cysts of adrenal-like structures. [T. L. C.]

4.—Simon Flexner discusses the **pathology of bubonic plague**, as observed in Hong Kong and San Francisco, describing six cases which came to autopsy. The chief distinctions are afforded by the lymphatic glands, and they will depend upon whether the glands were primarily or secondarily affected. Primary involvement may be of two kinds: of the first order, being the point of original reception of the virus; of the second order, representing the extension to a second, contiguous group of glands. Bubo of the second order are less marked than those of the first. Secondary buboes may be found in any or all glands, within the body, and at a distance from the primary lesions, infection having followed through the blood circulation. Primary buboes of the first and second order are described minutely, as well as tonsillar infections. The spleen in plague is enlarged moderately and the consistence is somewhat diminished. The color is deeper than normal, but it is not the type of the acute splenic tumor of the septiciemias. He emphasizes that, although the spleen in the autopsies made all contained bacilli, often in very large numbers, the cases themselves were examples of the bubonic and not of the septicemic variety *per se* of the disease. The morbid anatomy of the experimental disease in the guinea-pig is also given minutely. Two main types of the plague—bubonic and pneumonic—may be considered as established by the observations, of which a selected number have been given. In places where plague has secured a foothold, evidences of rat infection and probable rat dissemination have been brought forward. It is therefore the more

remarkable that in San Francisco, even after a year's prevalence among the Chinese, no evidence of a similar spread has been obtained. A comparison of the natural disease in man and the experimental disease in guinea-pigs as observed in San Francisco, with a description of the lesions observed in the plague in other places, will supply immediate conviction of the identity of the morbid processes. [T. L. C.]

5.—It. M. Pearce presents a contribution to the pathology of **leptothrix infection in man**, dealing with the leptothrixal necrosis of cartilage of larynx and a case of cholelithiasis and cholangitis. A histological description of the two cases in which these lesions occur are given, as well as an abstract of the literature. In a case of cholelithiasis there were found gall stones in the diverticulum of Vater and hepatic duct, as well as jaundice; slight cirrhosis of liver; fibroma of the kidney, chronic gastritis and arteriosclerosis. Leptothrix was the only microorganism in the concretions, and with the colon bacillus was found in large numbers in the bile. That the leptothrixal infection was of considerable duration, and not secondary to the operation, is indicated by the presence of the threads within the concretions. Experimental observations indicate that a mild catarrhal inflammation, yielding elements which unite with the bacteria to form a nucleus, greatly favors the production of concretions. Such a favorable set of conditions may be assumed to have been set up by the leptothrix, thus giving the basis for the concretion formation. Pearce suggests that these two cases, illustrating unusual and unexpected forms of leptothrixal infection, suggest, in that the members of the group of bacteria do not grow in culture media, or grow only with great difficulty or rarely, that a more extensive study of cover-glass preparations and sections might show the leptothrices to be of greater importance in lesions in man than has hitherto been supposed. In the first case, three processes, etiologically distinct, occurred. 1. Tuberculosis of the larynx second to tuberculosis. 2. Non-tubercular abscess of the submucosa of the larynx rupturing into the cavity of the larynx; probably pyococcal in origin. 3. An invasion of a portion of the posterior wall of the abscess by a leptothrix resulting in the disorganization of the cartilage of the larynx and involvement and perforation of the esophagus. The most difficult question to decide is the significance of the leptothrix invasion; whether the leptothrix caused the disorganization of the cartilage and the perforation of the esophagus, or whether this was due to the extension of the suppuration in the submucosa of the larynx. Pearce favors the former view. [T. L. C.]

6.—W. T. Longcope reports two cases of hepatic infarctions. 1. Thrombosis of the hepatic vein, secondary to metastatic gastric carcinoma with anemic infarction of the liver. 2. Thrombosis of the portal vein, secondary to metastatic gastric carcinoma with atrophic hemorrhagic infarction of the liver. The hepatic infarctions of this organ are rare, but do occur. They are of two types: **atrophic hemorrhagic and anemic infarctions**, the latter being the rarer. A detailed report of the autopsy and histological examination of the types in the two cases is given. Longcope believes that the condition in the first case depended largely upon thrombosis of the hepatic vein, and that the second case belongs to the class of atrophic hemorrhagic infarctions due to a thrombosis of a small branch of the portal vein. [T. L. C.]

7.—R. M. Pearce discusses the increase of elastic tissue in the lung in chronic passive congestion. His study has consisted in the examination, by Weigert's method, of a large number of sections taken from the lungs of healthy individuals and from lungs affected by chronic passive congestion. The tissues were hardened in Zenker's fluid, in alcohol, and in Orth's fluid. Pearce summarizes his studies by stating that in chronic passive congestion, the increase in density of the lungs is due, in large part, to the newly formed elastic tissue. This tissue is found to be increased in the finer structures of the lung in all cases of the disease, and in marked cases an increase is also observed in the pleura, intrapulmonary septa, blood-vessels and bronchi. The increase is progressive, depending on the age and degree of the congestion, and it apparently indicates an effort to strengthen the walls of the air passages, supporting the overburdened capillaries and preventing the collapse of the air-cells. [T. L. C.]

1.—Hordet first called attention to the fact that the serum of animals that had been immunized to certain albuminous substances, acquired the quality of producing a precipitate when treated *in vitro* with the solution of these substances. Buchner and Geret therefore undertook to test this fact with solutions of pure peptone which they prepared according to Kühne's method. They inoculated rabbits with solutions of this serum, and after a certain number of days withdrew the animal's blood, placed some of the serum in a test tube, and carefully covered it with a layer of peptone solution. This produced a distinct ring at the line of contact. When the solutions were mixed together a diffuse cloudiness was produced. This precipitate consisted of globulites. It was subsequently discovered that not only the serum of rabbits treated with peptone solutions, but also those treated with bovine blood gave the same reaction (the peptone was prepared from the fibrin of bovine blood), and the reaction occurred very much earlier than when the peptone solutions were employed. The method of obtaining the globulite is to inject about 5 ccm. of blood into a rabbit subcutaneously; then within 24 hours the blood is withdrawn, the serum obtained, and covered with a layer of the peptone solution. In about 12 hours a firm ring is formed at the point of contact, which consists of pure globulite. The formation can also be observed by mixing a drop of the serum and a drop of the peptone solution, and examining them in a hollow-ground glass slide. The crystals have a round or oval shape, and are strongly refracting. They vary according to the length of formation, from 2 to 35 *micron*, and in rare cases, after very rapid formation, sometimes, are not more than 1 *micron* in size. They are extremely resistant to all chemical destructive agents, failing to dissolve in boiling hydrochloric or nitric acid; they dissolve very slowly in sulphuric acid; and become yellow when exposed to tincture of iodine. They do not give mellow or the Bluret reactions. When burnt they leave an ash, and when treated with sulphuric acid this produces crystals of calcium sulphate. The authors believe that this substance will throw some light on the nature of immunity. [J. S.]

2.—Siegert, believing that the difficulty in treating infants with cow's milk, is rather due to the form of curds which are produced in the child's stomach, than to any specific difference in the chemical constitution, has experimented by feeding infants upon milk artificially curdled with hydrochloric acid, outside the body, according to von Dungen's method. The milk is thoroughly shaken with the acid, and then given in the ordinary way. He reports 8 cases of children who were either unhealthy or whose mothers had insufficient milk for nursing, and who suffered from various diseases such as pseudo-stenosis of the pylorus, congenital hypertrophy of the three tonsils, atrophy after prolonged dyspepsia, atrophy due to pertussis, rachitis. In some of these children there was obstinate vomiting that could only be controlled by improved diet. In the preparation of the milk Siegert prefers peptin, a preparation of the curdling ferments mixed with milk sugar. The diet occasionally causes constipation which may, however, be relieved by dilution or by massage. [J. S.]

3.—Lommel reports his experience in an institution for the care of deaf and dumb children, in which a boy developed scarlet fever in October, 1900. Five weeks later he

returned to the institute cured. In 21 days his room-companion was also attacked with the disease. He was returned to the institution in 2 months, and no case, apparently, was infected from him. The room was twice sterilized by formalin, and finally, in April, 1901, occupied by a child who 12 days later developed scarlet fever. The period during which the poison maintained its virulence was at least 133 days. The case is an illustration of the frequency with which contagion is carried by a third person. [J. S.]

4.—The commonest cause of the inflammation of the accessory cavities of the face is catarrh of the nose, or, in fact, any suppurative disease of the nasal cavity. In cases of disease of the frontal sinus with perforation into the orbit, the eye may be extensively dislocated without much alteration in its visual powers. Occasionally the cornea or the anterior portion of the eye, as a result of pressure and exposure to purulent secretion, becomes ulcerated. The following case shows the method of treatment in this condition. A man of 22 developed a swelling in the upper internal angle of the right eye, which was incised, and from which a considerable amount of pus was evacuated. Two years later the swelling again appeared, and was diagnosed as dropsy of the right frontal sinus. This was relieved by puncture, but 9 years later, after a severe cold, the swelling suddenly reappeared and was accompanied by extreme pain. Pressure produced purulent discharge into the throat and nose. There was some dislocation of the right eye. Incision was therefore made down to the upper edge of the orbit, the frontal sinus opened with a chisel, and the bone was found to be very thin and soft. The sinus was found to be filled with thick homogenous pus. The opening was then enlarged, the sinus washed and curetted, the ethmoidal sinuses thoroughly cleared out, a drain inserted, and the wound closed. It healed uneventfully and produced very slight, almost imperceptible deformity. [J. S.]

5.—Korff has modified the method of Schneiderlin of producing anesthesia by injections of scopalamine and morphine, using the injections at intervals of 2 hours, for a short time before the operation (.0004 scopalamine, and .01 morphine). Then during the operation a very small quantity of chloroform, perhaps not more than a third as much as that usually employed, is administered. The advantages are that the patients never suffer any anxiety, they never vomit; they can be awakened at almost any time during the operation without feeling any pain, and when they recover from the anesthesia they have no nausea, and can usually take Vichy water followed by soup or coffee, at once. The following night they usually sleep poorly, but are not restless, and the next day everything is normal. He has operated upon 80 cases by this method, and in 7 of these no chloroform was necessary. Much smaller doses should be used for children. [J. S.]

6.—Klaussner reports a case of bilateral congenital dislocation of the clavicles, at the edge of the sternum. There was no disturbance of the functions of the arms, and simply a deformity due to the prominence of the ends of the bone. No attempt was made to reduce them, but he suggests that possibly silver wire could be employed with benefit. [J. S.]

7.—Hoepfl reports some very curious surgical cases. The first, a solitary abscess of the liver, occurring in a woman, 33 years of age, who for some time had had attacks of prostration and a tendency to sweats at intervals of 6 weeks. Finally she developed severe pain in the abdomen and high fever. She was emaciated, the liver was greatly enlarged, and there was some edema over the hepatic region. Aspiration of the liver revealed the presence of pus; the abscess was incised, drawn, and the patient gradually recovered. The second patient, a woman of 33, had had a very difficult birth with application of forceps, leaving a fistula between the bladder and the vagina. Two operations failed to close this fistula, and permanent catheterization being impossible, the patient was directed to lie exclusively upon the abdomen. This resulted in rapid closure of the fistula, and the patient was discharged cured. The third case, a boy of 3 years, developed an enormous accumulation of fluid in the abdomen. At the operation a huge cyst of the mesentery was discovered, filled with dark brown fluid. The contents and wall of the cysts were removed and the patient rapidly

recovered. The 4th case, a child of 4 had swallowed some lye, and thereby produced a permanent stricture of the esophagus. It was impossible to introduce the sound, and therefore an incision was made into the stomach, and after the fistula was reduced, the sound could readily be introduced through the cardia which passed the stricture without difficulty. By this means a thread was passed through, along which tubes of increasing diameter were forced. He believes that the advantage of this operation is that the esophagus above the stricture is usually dilated, and therefore it is difficult to pass the end of the sound through it, whereas below it is contracted and the sound is guided directly to the opening. [J. S.]

8.—Schanz calls attention to the great importance of continually correcting the deformity in cases of habitual kyphosis. It is first important to render the spinal column thoroughly mobile and then to apply the plaster jacket which should be renewed at short intervals until the position of the spine is approximately normal. He reports the case of a girl of 18, treated by this method, in which the stature increased 4.5 cm. [J. S.]

9.—The following appear to be the conditions that should be fulfilled by any satisfactory method of illumination in educational institutions. First, the light should be sufficient in quantity, and well distributed; second, it should not alter the temperature and composition of the atmosphere; third, the source of light should not radiate much heat; fourth, the artificial light should not irritate the eye, and should not produce a sense of fatigue; fifth, there should be neither danger to life nor health from the nature of the light; sixth, the artificial light must be as cheap as possible. Seggel, discussing the methods of lighting, believes that these conditions cannot be fulfilled by petroleum, illuminating gas, and can only be adequately fulfilled by the Welsbach burner or the electric light. The Welsbach light he considers superior to the arc light, because it produces less heat and radiates laterally more satisfactorily. On the other hand, it produces a considerable amount of carbondioxide, and of course absorbs a considerable quantity of oxygen, at the same time requiring more attention on the part of the service. As to whether direct or indirect illumination is preferable, he considers that the former has the solitary advantage of illuminating a definite spot better, but is more blinding and produces more heat. In addition, some parts of the room are badly lighted, so that there is a continual alteration in the degree of illumination, which is exhausting to the eyes. Direct illumination, therefore, can only be used for single lamps, so placed that they throw the light from the left side. It is possible, however, by arranging the desks in a radiating manner around the source of light, to use one lamp for four pupils. Indirect light, on the contrary, has various advantages, producing a more uniform illumination of the room. The arc light covered by translucent shade is probably the best method by which this can be produced. [J. S.]

10.—Lenhartz continues his article upon septic endocarditis, and mentions a number of cases in which the disease followed septic infection of the ordinary nature, that had nothing to do with rheumatism. One of these cases is remarkable for the fact that although the patient was under observation for a number of months, and at the autopsy numerous vegetations were found upon the aortic valve, no murmur had been heard at any time during the course of the disease. He does not believe that we can discriminate between staphylococcal and streptococcal infection by the type of temperature. The diagnosis of the condition is to be made from the presence of symptoms of sepsis and a murmur in the heart; and is confirmed by the existence of a palpable tumor of the spleen. The prognosis, although very grave, is not hopeless, as the 4 cures in the 38 cases observed by Lenhartz, prove. The treatment is in a very satisfactory state. Marmorek's serum is of no value and the other methods that can be employed give little better results. [J. S.]

1.—There has been a general tendency on the part of pathologists to deny the possibility of rupture of the valves in the human heart as a result of external violence. Strassmann records a case which he thinks shows definitely that this can occur. A man of 65, who, so far as could be told, had been previously in good health, was kicked in the chest by a horse. Soon after this he showed signs of marked cardiac insufficiency, and six months after the accident he died of cardiac failure. The clinical signs are not given in detail. The post-mortem showed as the lesions of chief interest healed fractures of the fifth to the eighth ribs on the left, adherent pericarditis, sclerotic patches on the valves and aorta, a rupture of the intima and partial rupture of the media of the aorta, just above the valves, 2 cm. long and 1 cm. wide, in the middle, running obliquely across the vessel, and at one end advancing into the anterior aortic leaflet, the latter showing an irregular tear, with rounded, healed edges. The advance of the symptoms of cardiac insufficiency after they appeared was a very rapid one, an observation which is in accord with reports of similar cases; cardiac lesions supposedly following forcible injury being, as a rule, followed by very rapidly advancing signs of lost compensation. [D. L. E.]

2.—Talma first discusses the previous literature concerning the antiseptic action of the bile. The results of study have been varied. Talma then reports a series of experiments upon rabbits, consisting of direct injection into the exposed gall-bladder of bacteria of various species and virulence. The injections were made through a hollow needle. He recommends carrying out the operation in a warm bath of normal salt solution, as this avoids shock and drying of the peritoneum, etc., and the results are consequently more satisfactory. He found that the bile contained some substance which interfered with the development of most varieties of colon, typhoid and diphtheria bacilli, the different bacteria varying greatly in their susceptibility to the unfavorable influence of the bile. The virulence of the bacteria is, he states, not a term which is synonymous with their power of producing infection of the biliary passages. The bactericidal action of the bile varies at different times and with different animals. One of the most important factors influencing the result of the injections was the number of bacteria that reached the bile passages. The liver cells and the epithelial cells of the bile passages strongly resisted any attempt at entrance on the part of bacteria; this was particularly striking with diphtheria bacilli. In some instances he observed infection of the subjacent tissues about the puncture wound, while the large number of bacilli in the gall bladder had effected no entrance over the surface, where the epithelium was intact. If the bacteria in general were introduced in very large numbers, they usually caused local necrosis, however, and very rapid death; if they were introduced in small numbers the animal lived, and when killed showed some remnants of a more or less slight inflammatory process, but the bile passages were sterile. [D. L. E.]

3.—The knowledge of the normal amount of hippuric acid excreted, as well as that of amounts under various pathological circumstances, has been very indefinite. This led Lewin to investigate normal condition, as well as those under the use of drugs and varied diets and in various diseases. He used the method of Salkowski and Blumenthal, having found that of Bunge and Schmiedeberg unreliable.

With a mixed (though somewhat limited) diet of normal quantity, the daily amount of hippuric acid varied from 0.10 to 0.30 gm. The quantity was increased daily by using glucose in the diet, possibly as a result of increased intestinal decomposition. Large amounts of albuminous food, though increasing intestinal decomposition, increased the hippuric acid. The use of cholic acid increased the hippuric acid, and in many instances the uric acid was at the same time decreased. It is, therefore, possible that there is a parallelism between the excretion of these substances. This portion of the investigation was undertaken because cholic acid forms benzoic acid in the organism, and benzoic acid unites with glycocholic acid to form hippuric acid. It is thought by some authors that glycocholic acid by synthesis with cyanic acid forms uric acid. If this were true the use of any substance furnishing benzoic acid in the organism ought to decrease the uric acid. This was, as stated, found to be the case in some instances. Food rich in nuclein (thymus) increased the output of hippuric acid and at the same time caused an increase in the uric acid; the increase in hippuric acid was attributed to increased intestinal decomposition. In gout and diabetes the hippuric acid was normal, in perityphlitis, owing to intestinal disturbance, it was increased. The hippuric acid was never decreased, and was in most cases increased in febrile conditions. In renal disease it was almost always increased; never decreased. This is a point against the theory that the kidneys are the only seat of the formation of hippuric acid. [D. L. E.]

4.—Wolff directs attention to the imperfections of the usual method of determining whether a fluid in a serous cavity is an exudate or a transudate. He finds that these fluids can be divided into two great classes, on the basis of microscopic examination—(1) Those in which one finds practically only polynuclear white blood corpuscles with a very few red cells. (2) Those which contain no polynuclear leukocytes, or at most very few, but do show numbers of lymphocytes and red blood cells. The first class of fluid occurs with inflammatory conditions; the second with circulatory failure, i. e., in conditions in which one would expect a passive leakage from the vessels. Wolff thinks that microscopic examination is a much better method of distinguishing between exudates and transudates than determining the specific gravity, the amount of albumin and the reaction. The serous fluid formed in tuberculous pleurisy corresponds to Wolff's class of transudates. Such fluid is often found when the pleura itself is free from tuberculosis or any inflammation. Wolff therefore theorizes that the fluid is a transudate, and its escape is due to vascular changes caused by the toxins produced by the tubercle bacillus. [D. L. E.]

5.—Mohr directs attention to the fact that febrile disease may have one of two influences upon diabetic glycosuria; the increase of sugar may increase or diminish. In some cases no influence is exerted. It is always of absolute importance to know exactly what diet the patient was taking before, during and after the intercurrent disease, as otherwise changes in diet may have caused the changes in the glycosuria. Mohr reports six cases in which changes in the amount of sugar-forming food could not have caused the changes in the glycosuria. In all but one instance the diabetes was of the mild form before the occurrence of the complicating febrile affection, and in four instances the latter affection was itself mild in character. In two cases a temporary decrease in the tolerance for carbohydrates was noticed, but the previous conditions soon reappeared. In the other cases the previous tolerance was much reduced, and was regained only after a long period; in one the tolerance was permanently reduced, while in the remaining case, which up to that time had been of favorable course, the occurrence of phlegmonous angina caused a rapid and uncontrollable increase in the glycosuria and general symptoms, and signs of acid intoxication soon appeared. Mohr, therefore, states that in cases in which the glycosuria is increased one must remember that this may be, as it frequently is, only a temporary change, but it may also be a permanent change, and even a mild intercurrent disease may convert a mild diabetes into a severe and uncontrollable case. Evidently in such cases the febrile process directly damages the function of the organs engaged in carbohydrate metabolism. The fact that infectious febrile disease sometimes causes a decrease, sometimes an increase, of glycosuria has been explained by Richter by showing that increased temperature of itself causes hyperglycemia

and glycosuria, while bacterial infection (as distinguished from bacterial fever) causes a decrease of the sugar of the blood. The observations recorded by Mohr as well as previous experimental and clinical records, make it quite clear that we should earnestly consider infectious diseases among the direct causes of diabetes. [D. L. E.]

6.—Volhard reviews the work done concerning the presence of a fat-splitting ferment in the gastric juice, and discusses his own previous work. He has expressed the opinion that in an egg-yolk-glucose mixture the formation of a layer of clear fat on the top of the mixture after exposure to the action of gastric juice was due to a fat-splitting ferment acting upon the emulsion of fats and setting free fatty acids. This, however, he has recently become convinced was erroneous. The formation of the layer of clear fat has nothing to do with the production of fatty acids, and is merely a breaking up of the emulsion and consequent floating of the fat on top, and is the result of the presence of considerable amounts of HCl. By working with dogs, in which a gastric fistula had been established by Pawlow's method, he convinced himself, however, that a fat-splitting ferment (i. e., a ferment that produces fatty acid from neutral fats) is present in pure gastric juice. The method of obtaining the gastric juice excluded any possibility of admixture of pancreatic secretion. The ferment, like pepsin, is produced chiefly in the fundus of the stomach, and may be extracted from the mucous membrane of the fundus by glycerin. The ferment passes through a porcelain filter. It is very sensitive to the action of a strong pepsin-HCl mixture, and if the mixture be sufficiently strong or its action, sufficiently long continued, the fat-splitting ferment is entirely destroyed; the peculiarity possessed by fatty foods of exciting a gastric secretion which is poor in pepsin and HCl is perhaps due to this sensitiveness of the fat-splitting ferment to pepsin and HCl. Volhard thinks that the demonstration of the presence of a fat-splitting ferment in the gastric juice strongly indicates that Pflueger is right in his claim that all neutral fats must be split up before they are absorbed. [D. L. E.]

7.—Bernstein reviews the previous opinions concerning a possible etiological relation between rheumatism and trauma. There has been much doubt about the existence of any such relation, but Bernstein is confident that trauma is active in determining the onset of rheumatism, and in support of his work refers to experimental work concerning infectious arthritis, and also reports seven cases in which a damaged joint soon after an injury showed an acute arthritis, accompanied by fever, and subsiding upon the use of salicylates. The trauma is usually a single severe one—either an infected wound of the joint, an infected skin wound, a subcutaneous injury of the joint or other subcutaneous injury. The infected wounds of joints rarely or never lead to rheumatism, but often cause pyemia; infected skin wounds usually cause pyemia, but occasionally lead to rheumatism. Subcutaneous injuries rarely or never cause pyemia, but very frequently cause an outbreak of rheumatism. In collecting his cases and drawing his conclusions from a study of the literature, Bernstein has confined himself to those cases in which a first attack of rheumatism appeared soon after a trauma; recurrent attacks, as he says, may be only accidentally associated with an apparently etiological factor present at the time, and should, therefore, not be used in any such argument. There are no very marked peculiarities in the cause and symptomatology of traumatic rheumatism, and he does not make the diagnosis from traumatic arthritis very clear. He considers that in legal proceedings for damages following accident it should be recognized that rheumatism may be directly caused by an accident, and consequently heart disease may be indirectly due to the same cause. [D. L. E.]

8.—Waldvogel and Hagenberg report a series of estimations of the acetone in the urine of a number of subjects, and give figures which show a decided increase of the acetone to above even high normal figures, after the use in a normal mixed diet, of additional quantities of butter, ranging from 50 to 150 gm. in the day. This they term an alimentary acetonuria. It is particularly insisted that the diet was sufficient in amount, and that this was, therefore, not an acetonuria of inanition. The authors are inclined to consider the acetonuria as of enterogenous nature, though they admit that there is no proof of this, and it may have been produced from the fats after their absorption. At any rate, there are two very different forms

of acetonuria—one is due to rapid destruction of body fat, the other to the presence of large amounts of fatty acids in the intestine. The authors also state that they compared figures obtained by the Messinger-Huppert method with those given by Waldvogel's method, and found that they differed by only a few milligrammes. Hence they consider Waldvogel's method thoroughly reliable. [D. L. E.]

9.—After a very interesting study of the HCl curve at various periods after varied test meals (coincident studies of the chlorides in the food, the total chlorides in the gastric juice, and then by difference, the total chlorides secreted) and coincident studies of the freezing point of the gastric juice and of the various foods used, Justesen concludes that we may say that gastric digestion goes on much as follows: After brief salivary digestion many soluble substances go into solution. The gastric contents thereby become almost always strongly hypertonic; hence a secretion of water and HCl sets in at once, and, through osmosis also, many substances in solution (such as pepsin, sugar and alcohol) are, to a greater or less extent, absorbed. The first portions of HCl are combined at once, with the albuminous chiefly, afterward with the weaker organic bases, and with bases already combined with CO₂. After this the HCl becomes apparent as free HCl, and this HCl and the NaCl secreted henceforth are (physically) only for the purpose of equalizing osmotic tension. The "vital diluting secretion" of the epithelial cells of the stomach reduces the molecular concentration of the gastric juice considerably below that of the blood. During this latter period properly prepared food portions of the gastric contents are being expelled into the duodenum, while the more solid portions are retained. [D. L. E.]

11.—Pollatschek thinks that previous statements concerning the morbidity of the Jews in relation to diabetes mellitus are of little value, as there is never any statement as to the relative number of Jews and Christians in the clientele of the reporter. Pollatschek states that in ten years he has treated 4714 persons, 2381 of whom were Christians, 2333 Jews. There were 653 diabetes, 289 of these being Christians and 364 Jews; i. e., reckoned by the number per thousand of all patients, 124 Christians and 155 Jews had diabetes. Of four cases of coma three occurred in Christians, and severe complications occurred almost exclusively in Christians. This, he believes, indicates that Christians do not go to sanatoria so early as the Jews, and consequently as bath-physician he saw more bad cases in Christians than in Jews. He also directs attention to the fact that diabetes is common in England, where there are few Jews, and ends by stating that he doubts the truth of the generally accepted statement that Jews are especially susceptible to diabetes. [D. L. E.]

2. The Influence of Some Substances upon Trommer's Test. COLLINA.
3. The Biological Demonstration of Vegetable Albumin. A. KOWARSKI.
4. A Case of Sepsis with Otitis and Sinus Thrombosis Beginning with the Symptoms of Articular Rheumatism. SCHNELLE.
5. Topography of the Brain. WALDEYER.
6. The System and Therapeutic Employment of Heat Conveyance. S. MUNTER.

1.—Bettmann describes a variety of chloracne which he has observed among a number of workmen in a chemical factory. There was a diffuse formation of comedones over the whole body, a dirty gray pigmentation of the face and a dry rough skin. The cause of the chloracne was attributed to a mixture of tar derivatives with fumes of hydrochloric acid. He states that further observations are required for the purpose of prophylaxis and therapy. [M. R. D.]

2.—Investigations in the Chemical Laboratory at the University at Berlin showed that creatinin is not the only cause for the yellow precipitate of copper oxihydrate, but that concentrated forms of guanidin-carbonate, glykocyanin and glykocyamidin also produce this phenomenon. [M. R. D.]

4.—Schnelle reports a case of sepsis with otitis and sinus thrombosis beginning with the symptoms of articular rheumatism and occurring in a man who had never been previously ill. It was a question whether it was a

case of sepsis of otitic origin beginning with articular rheumatism or sepsis with involvement of the middle ear. Bacteriological examination of the discharge from the ear as well as the thrombosis removed from the jugular vein showed delicate diplococci. In the discharge from the ear some streptococci were also found. The bacteriological examination, however, could not determine whether the sepsis had originated from the ear or not. [M. R. D.]

5.—To be concluded.

6.—To be concluded.

3.—Experiments in the Institute for Medical Diagnosis at Berlin analogous to those performed by Wassermann, Uhlenhuth and others with vegetable albuminous bodies showed that these also give rise to the occurrence of antibodies but that they cannot be as easily differentiated as those belonging to the animal kingdom. [M. R. D.]

July 11, 1901.

1. Demonstration of Preparations from Animals Infested with Tuberculosis and Treated with Hetol and Iga-zol. MAX WOLFF.

3. The Transitory Mental Disturbances of Hysterical Origin. M. SANDER.
4. The Topography of the Brain. (Conclusion.) WALDEYER.
5. The Method of the Therapeutic Use of Heat and Heat Centralization. S. MUNTER.

1.—Wolff has treated rabbits with subcutaneous and intravenous injections of hetol (cinnaemic acid), and with inhalation of igazol, after having rendered the animals tuberculous. In studying the effects of hetol injections he used direct inoculation of the anterior chamber of the eye, so that he might watch the disease during the cause, and also used injection by inhalation and by intraperitoneal injection. With igazol inhalation infection was used. In no instances could he see that the lives of the animals were prolonged by using the drugs, or that macroscopic or microscopic preparations of the tissues showed any greater tendency toward healing in the animals so treated than in controls. In human subjects he has seen harm rather than good as a result of both forms of treatment, and he also states that in animals igazol inhalation caused severe pulmonary congestion and even pneumonia. [D. L. E.]

2.—Schrötter reports a case in which he found a severe stenosis of the trachea near the point of its bifurcation. Portions of the tissue removed from the diseased area showed the presence of tuberculosis, and, since the patient presented no signs of disease of the lungs, and the stenosis caused severe and distressing dyspnea, portions of the diseased tissue were removed at different sittings, and the patient's condition was much improved. But there was a constant tendency to slight increase in extent, and this and, still more important, the contraction of the scar tissue rendered any attempts at permanent relief fruitless. Schrötter finally had some hollow tubes of slightly conical shape, with a slight, spindle-like constriction, made, and at first introduced one of these, left it free for a short time, and then withdrew it. Much improvement followed this dilatation, and finally he was able, with the aid of a special instrument, to introduce a tube, leave it in the stenosis, with a string attached, and withdraw it only after several hours. Very great improvement followed. The irritation resulting from the treatment and fear of pressure ulceration obliged him finally to stop the treatment, and the patient was sent home and several months afterward reported that she was very comfortable. Schrötter thinks that the main reason a complete cure was not obtained in this case was that the disease was of tuberculous origin. He believes that benign stenosis might be cured by a similar procedure, and that there should be more active effort to treat surgically cases of disease of the deeper respiratory passages by the aid of the tracheoscope. [D. L. E.]

3.—Sander reports four cases in which mental disturbance appeared suddenly without prodromal symptoms, and vanished as suddenly after a few hours or at most days. Physic disturbances were wholly absent both before and after the outbreaks. Two of the patients were young servant girls who had a neurotic family history, and were of neurotic temperament. The third was a nurse also of neuropathic family. The fourth was a young soldier whose mother had some nervous affection, and who was excessively sensitive. In the first three the outbreak oc-

curring after love troubles, in the soldier after being roughly abused for his clumsiness in drilling. Two of the girls attempted suicide, and all three showed great excitement, with entire lack of recognition of surrounding objects or persons. In the nurse, who was injured in her attempt at suicide, a second period of psychic disturbance of two weeks' duration occurred about three weeks after the first attack, and the outbreaks in all the other patients were only of a few hours' duration. The soldier showed only profound stupor, without any period of excitement. None of the patients had the slightest recollection of the attack itself or of what occurred during the attack. One servant girl showed complete analgesia during the attack, and all the girls presented the picture of an acute hysteria. These facts and the character of onset and disappearance of the attacks, the family and personal history and the character of the hallucinations convince Sander that they were all hysterical, and he believes that no other diagnosis is satisfactory in the case of the soldier. He considers that many instances of suicides, particularly in overworked servant girls and in those who have had any emotional excitement, are due to acute hysterical psychosis, and that a proper recognition of such a possibility and the gravity of signs of acute hysteria may prevent many suicides.

1.—Will be abstracted when finished.

2.—Will be abstracted when finished.

3.—In the case of a soldier, aged 22 years, who was suffering from grave jaundice, it was discovered that both his mother and his father, as well as a maternal aunt had died of diabetes. The patient had recovered from a left-sided pneumonia with serious infectious symptoms. But, after participating in a series of military maneuvers, he became depressed and complained of erratic pains in his limbs. He lost flesh and finally had a chill, accompanied by a stitch in the right side and vomiting. The examination showed congestion of the base of the right lung with cardiac asthenia and anuria. Later, jaundice appeared, which was at first slight, but which subsequently became marked. The liver became hypertrophied and the spleen was also enlarged. During the progress of the case there was a crisis of eclampsia, subcutaneous hemorrhages in various situations, bloody diarrhea, typhoid symptoms and, finally, death. From a study of the case in the light of autopsy, Woirhaye and Caziot consider that his parents transmitted to the patient a dynamic disorder of the hepatic cells that rendered his liver easily susceptible to infectious influences. The privations of the patient, supplemented by the infectious influence of a serious pneumonia, overtaxed the liver and the toxins that should have been eliminated by that organ were thrown into the general circulation and served to render less resistant an already incompetent liver. Finally, a series of military maneuvers, by producing the toxins of fatigue, exhausted the already overtaxed organ. The infecting agent may have reached the liver either through the hepatic artery or through the bile ducts. The absence of micro-organisms in the blood during life was due to the phagocytosis of the increased number of leukocytes in the blood. There were, however, bacilli in the spleen, in the lymph-nodes at the hilum of the liver and in the liver itself that resembled the bacillus coli communis in morphology and the sub-normal temperature was a further indication that this organism was responsible for the jaundice. Further study

shows that the liver cells were only able to continue their bile-making function, and that their other activities were destroyed. The kidneys were also affected by the disease. The urea, the chlorides, the phosphoric acid and the total nitrogen were reduced. The urine contained bile and albumin, but no sugar. The defense of the organism in the liver was attempted, as shown on histologic examination by congestion, positive chemotaxis, intense diapedesis and phagocytosis and compensatory hypertrophy. The same process was found in the kidney with the exception of the hypertrophy. There was a leukocytosis and an hypertrophy of the lymph-nodes which served as an attempt at the defense of the organism in general. [J. M. S.]

4.—In four patients suffering from severe scarlet fever, Roger discovered pericardial friction sounds. Albuminuria was present as a complication of scarlet fever in 143 individuals. At the isolation hospital of the *Porte d'Aubervilliers* the author observed a case of scarlet fever in a woman in the seventh month of pregnancy. The disease did not interfere with the course of gestation. In one case scarlet fever developed coincidentally with pneumonia and in another case with diphtheria. In one patient suffering from scarlet fever, albuminuria appeared during convalescence and in 10 days no albumin could be detected when a part of the urine for 24 hours was examined. But when the various specimens were examined as they were passed, it was found that some contained albumin while others were free from it. It was then found that, when the patient stood, albumin appeared in the urine. Also, both bread and meat caused albumin to appear in the urine; later, however, bread could be eaten without producing albuminuria, but meat continued to produce the symptom. Again, every time the patient took a bath albumin appeared in his urine. The mortality was 2.5%. In 6 cases death was due to the intensity of the infection. There were 4 cases of puerperal scarlet fever, of which 2 died and 2 recovered. There were 5 cases of measles in the hospital and 117 cases of chicken-pox. In 3 cases of chicken-pox the bullæ reached unusual dimensions. In one of these cases the large bullæ appeared on a portion of the skin that had previously been irritated by a mustard plaster. There was one case of hemorrhagic chicken-pox in a little girl who was convalescent from purpura. The following complications of chicken-pox were noted: one case of laryngitis due to the eruption in the larynx, 2 cases of slight albuminuria and one of otitis media. Six of the patients died, 2 of intercurrent miliary tuberculosis, one of bronchopneumonia, one of furunculosis and intense pyoderma, one of postinfectious cachexia, and one of pyemia. From 1896 to 1900 the death-rate from chicken-pox in this hospital was 3.93%. There were 207 cases of sore throat, of which 70 were cases of diphtheria. Of the latter 17 were complicated by albuminuria and 8 by paralysis. Of the patients attacked by paralysis 4 died. [J.M.S.]

5.—Albert reports the case of a man, aged 17 years, who was employed as a gardener in a city of Algiers. He had had a number of attacks of malaria. Between his malarial attacks the patient had apparently been in perfect health. He had an attack of malaria in January, 1900, and in May of the same year he began to have fever again; but this time the attacks were irregular, without defined type and suddenly were complicated by very sharp pain in the left side. The patient was profoundly anemic and his expression was one of anxiety and pain. In the left side, 3 fingers' breadth below the ribs there was a rounded tumor that evidently contained fluid. On opening this abscess a large quantity of pus was evacuated and the exploring finger entered a cavity in the substance of the spleen. After the operation the patient entered convalescence, which was complicated by an attack of pneumonia. Bacteriologic examination of the pus showed that it was sterile. Histologically, the contents of this abscess of the spleen consisted of small polymorphonuclear, neutrophilic leukocytes. [J. M. S.]

6.—Pic and Cadé report the case of a man, aged 50 years, who had had 2 attacks of pericarditis. He was admitted to the hospital complaining of unproductive cough, oppression, and painful swelling in the region of the liver. The area of cardiac dullness was markedly increased, but not displaced by a change of the position of the patient. On auscultation the sounds were regular, accelerated, dull and distant and with the rhythm of the fecal heart. There were no murmurs. The veins of the neck were swollen; the

pulse was small, rapid, regular and 136 per minute. It presented the character of *pulsus paradoxus*. The liver and spleen were enlarged. The urine was pale, but contained neither albumin nor sugar. The authors made a diagnosis of *symplysis of the pericardium*. The administration of digitalis was not beneficial, edema of the lower extremities and of the scrotum appeared and, in spite of treatment, the patient's condition grew worse and he died. At autopsy the diagnosis of *symplysis of the pericardium* was confirmed. The pericardium was attached to the thoracic wall, to the neighboring lung and to the tissues of the mediastinum by numerous adhesions. The nerve fibres which passed through the connective tissue were more or less sclerosed. Although there was no valvular lesion, the walls of the heart were thickened and its cavities were dilated. In the neighborhood of the anterior wall of the right auricle there was a rounded tumor. The portion of the superior vena cava near this tumor presented thickened walls so that its opening into the auricle was perceptibly narrowed. The heart and pericardium weighed 520 grams. Microscopically, there was a thick layer of fibrous tissue on the surface of the heart, due to the pericardial disease. Beneath this fibrous tissue there were extensions of the sclerotic process into the myocardium producing atrophy, fragmentation and thinning of the muscle fibers. The tumor of the right auricle presented the histological character of *tuberculous inflammation*, although no tubercle bacilli could be demonstrated in it. The authors believe that the *symplysis of the pericardium* was due to a tuberculous process. [J. M. S.]

1.—Operation for tumor of the kidney is now the usual treatment. The main operation performed is *nephrectomy*. This was done by Riedel in Jena by the transperitoneal method, in 13 out of 15 cases. Five of these cases died. Six of the tumors were immovable, in two lumbar operation was performed, with one death. Three of them died a short time after the operation. Seven tumors were movable. The diagnosis was comparatively easy in 13 cases. In the two other it was exceedingly difficult, as tumors of the upper and middle half of the kidney are not palpable. The 15 case-histories are given in full. Pathologically, out of 11 tumors which were examined, seven were composed of suprarenal tissue, many containing cysts. There were one cystadenoma, one diffuse carcinoma, one papillary carcinoma of the pelvis, and one adeno-carcinoma of the pelvis of the kidney. Symptoms had existed in one case for three years, in a floating kidney; in two cases for two years; in six cases, from one-half to one year; and without any symptoms in three cases. The tumors varied from the size of a goose egg to a child's head. Hematuria occurred in six cases out of seven with suprarenal struma, and in two of the other cases. It is striking that none of these renal tumors occurred in children, and that none of them were sarcomata. In the clinic books, six cases of children with tumors of the kidney were found, but they had advanced too far to be operable. Metastases existed in other adult cases, so that operation was contraindicated. The lasting results are as follows:

Of one case, nothing is known; five died from one-quarter to two and a half years since operation; three are yet living, from one to five years since operation. After thus discussing tumors of the kidney from a therapeutical, clinical and pathological standpoint, Grohé insists that when hematuria occurs, the physician should consult a surgeon immediately, in order that *nephrectomy* may be performed as soon as possible, should it become a necessity. [M. O.]

2.—Justian reports a case of *tuberculosis in a right-sided inguinal hernia*. This is the twenty-ninth case reported. A soldier, in his second year of service, 22 years old had noticed the hernia two weeks before. Pleurisy with effusion appeared on the left side. An exploratory puncture was made, the liquid containing mononuclear leukocytes. Thoracotomy followed. Tubercle bacilli were never found. Two months later, the Bassini operation was performed, a *tuberculous sac* being extirpated. This tuberculous exudate in the hernial sac was probably secondary to that in the pleura. Three varieties have been differentiated, the commonest, with miliary tubercles; next, with nodules formed of coalesced tubercles; and rarely with the formation of septa. The diagnosis has only rarely been made before operation. Twenty-four of the 29 cases were treated surgically. Of the 24 operations, 16 cases recovered. If the testicle is also affected, it should be removed. [M. O.]

3.—Stierlin reports the case of a man of 25, with a *racemose arterial angioma* of the supraorbital region. It was about the size of half a plate, and many modes of treatment had been unavailing. It was soft, and pulsated. He ligated its entire circumference, each suture being put in place before the preceding one was secured. The bleeding stopped when the sutures were tightened. Ten days later, Stierlin excised the tumor. It healed and has not recurred. His next case was a *traumatic aneurysm* of the left femoral artery, in a man of 26, following a shot in the thigh. The tumor was as large as an orange. The aneurysm was extirpated. The preparation showed that the inner wall of the artery was not perforated by the bullet, the outer wall of the artery forming the sac of the aneurysm. He rapidly recovered. The third case was an *aneurysm* of both common iliac arteries, in a man of 49. The pulsating abdominal tumor grew enormously until death occurred. At the autopsy it was seen to be 36 cm. long and 19 cm. wide and deep. It was probably arterio-sclerotic in character, for plates of atheroma were found in the abdominal aorta only. But few such cases are seen early enough for operation. [M. O.]

4.—After a short review of the literature, Gessner reports the results of his examination of eight tumors of the testicle. Four of them were sarcomata, the other four, *teratomata*, containing embryoidal tissue. The case-histories and pathological examinations are given in detail, with drawings. Three tumors were very similar. While the tissue was irregularly arranged, there were many small lobules, with septa of fibrillar connective tissue. About the testicle the tumor seemed benign, about the epididymis, malignant. Products of all three embryonal layers were seen in these lobules. Nervous tissue, representing the ectoderm, was seen in two of the tumors, as were cysts with cylindrical and columnar epithelium; the endoderm was represented by intestinal glands and follicles; and the mesoderm, by unstriated muscle, cartilage, bone, and fibrillar connective tissue. The fourth case was different, not at all embryoidal in character. It was full of canals, cysts, with mixed epithelium, almost adenomatous. But all four tumors arose from the corpus Highmori; all are divided into more or less well recognized lobules, containing signs of the three embryonal layers, in the first three tumors only. The fourth case showed typical carcinomatous degeneration. All were congenital. They were malignant of themselves. There may be metastasis and recurrence, and all three embryonal layers occur. The best differentiated tissue is found toward the edges of the tumor. Much such tissue exists, so that products of the three embryonic layers develop, proliferating unlimited. A brief report of yet another embryoidal tumor is appended. [M. O.]

5.—Weber reports ten more cases of *subphrenic abscess*, five of which followed appendicitis. In two cases the subphrenic abscess was retroperitoneal, in four others intraperitoneal in position. Subphrenic abscess may develop

in one of four ways—along the ascending colon; along the appendix; as a secondary abscess in general peritonitis; or extraperitoneally, from the retrocecal tissue. Prompt operative interference in appendicitis will prevent the development of subphrenic abscess. One case followed a bullet wound; one, a perforated gall bladder; another, a suppurating echinococcus cyst in the liver; and the last, a putrid bronchitis. The last was the only fatal case. The case-histories are given in full. [M. O.]

6.—Payr describes fully a rhinoplasty performed upon a man of 60, who had cancer of his nose. The tip of the nose, the major part of both alae nasi and of the septum were removed with the tumor. The technique of the flaps cut and the details of the operation are described and illustrated by excellent drawings. This remarkable case, in a man with a full beard, presented many difficulties. Yet the result was splendid. [M. O.]

7.—Schultze reports three cases of **exarticulation of the larger joints**. The only danger is hemorrhage. He used the large forceps of the Richelot-Doyen pattern, seizing each separate muscle with them, thus stopping all bleeding. His results have been satisfactory. (M. O.)

8.—Petersen, in performing gastroenterostomy, says that the piece of the jejunum used must be very short (3 to 10 cm.). But in this case the gastroentero-anastomosis must lie deeper than the duodeno-jejunal fold; there must be something to show that the length chosen is correct; and some cause to prevent the intestinal contents from flowing backward. Now Kelling believes that it is rarely possible to fulfill these conditions. When cicatrization occurs, the position of the gastroentero-anastomosis will be above the duodeno-jejunal fold. A longer piece of the jejunum should be selected, to prevent the backward flow of the intestinal contents, by making the loop larger; that another bit of small intestine does not enter the loop and obstruct it; and that digestion may not be hindered so much, *thereby* the food does not pass through the duodenum. Kelling reports a case, a woman of 48, in whom half of the stomach had been resected for cancer of the pylorus. Gastroenterostomy was performed by the Hacker method, with a Murphy button. Through a fistula which resulted from the removal of gall-stones, later, it was seen that bile and pancreatic juice flowed backward, up to the stomach, whenever any food was ingested. This showed that the intestine (over 50 cm. long) of the gastroentero-anastomosis was filled with stomach contents. After great care, the fistula healed and the patient recovered. [M. O.]

9.—There are but three methods of determining the etiology of carcinoma and sarcoma. Neither bacteriology nor clinical observation has given satisfactory conclusions. Ritter believes that it remains for pathology to solve the problem. For certain facts exist in pathology which point directly to an infection as the cause of malignant tumors. Actinomycosis, tuberculosis, etc., were considered tumors before their infectious nature was discovered. While carcinoma and sarcoma may be the result of the reaction of normal tissue to an infection, this is impossible in the metastases. The chromatin in the nuclei of malignant tumor cells is the same as in normal tissue. Nor is karyokinesis a sign of malignancy. The asymmetrical mitosis figures simply show sick tissue, not necessarily malignant tissue. Nor can malignancy or benignancy be determined from the cells, histologically. The literature is full of examples of adenomata, in which no secretion, but degeneration fills up the cavities. In carcinoma there is no secretion, as in normal tissue, except when inflamed. Degeneration and necrosis only occur when the blood-supply is in any way cut off, sometimes very late. Necrosis, as in the infectious diseases, is found in the center of the tumor, surrounded by inflamed tissue, but the occurrence of metastases cannot be explained by the infectious theory. After repeating numerous theories, Ritter states that, from the pathological findings, the possibility that carcinoma and sarcoma are infections cannot be denied. The analogy seems probable in sarcoma, but there are many objections to it in carcinoma. The degenerations back up this view. He thinks it possible that the bacteria which cause these tumors have already been found, but were not recognized. [M. O.]

10.—Beck reports three cases of fracture of the coronoid process of the ulna, a condition which he believes occurs

frequently. The case-histories, with Röntgen photographs, follow. [M. O.]

11.—Mallefert reports a case of **upward dislocation of the patella**, which occurred 15 years ago, in a man then 40 years old. Examination now shows that the ligamentum patellae was not separated, as it can yet be felt crossing the knee-joint, lengthened and hard, with the patella upon it, above the joint. [M. O.]

VRATCH.

July 28, 1901. (Vol. XXII, No. 30.)

1. Pentose in the Animal Organism and the Origin of Pentosuria. N. P. KRAFKOFF.
2. The Significance of the Theories of Acid-Intoxication in Relation to Internal Pathology, and Especially to the Origin of Hematuria. V. F. ORLOWSKI.
3. The Casuistic of Traumatic Injuries to the Brain. A Case of Motor Aphasia. M. S. MASLOWSKI.
4. A Rare Case of Hysteria. I. A. R. MAROWSKI.

1.—Will be abstracted when concluded.

2.—Orlowski performed a number of experiments which seem to disprove the theory held by a number of authorities that hematuria as well as some forms of auto-intoxication are the result of an abnormal accumulation of acids in the blood. Having produced artificial hematuria in dogs by ligating the ureters, he examined the alkalinity of the blood by the accurate method of Lowey. He found, as did the adherents of the acid-intoxication theory, that the alkalinity of the blood was markedly diminished, owing to an accumulation of acids. But this diminution is the result and not the cause of the hematuria. To prove this, he adduces the following observations: In 3 cases of hematuria in man he found that the diminished alkalinity of the blood followed and not preceded the attack. Moreover, in diabetes and cancer the alkalinity of the blood is markedly diminished, and yet no hematuria is produced. He, therefore concludes that various observers have mistaken the effect for the cause. With regard to acid-intoxication, the author denies that the presence of ammonium salts in the urine have any significance. The presence of acetone and diacetic acid, substances but slightly poisonous, is only a secondary manifestation of disturbed metabolism. There are only two conditions indicative of acid intoxication: (1) The presence in the blood and urine of B. oxybutric acid and (2) the improvement following the administration of alkalis. These conditions have been observed only in diabetic coma. [A. R.]

3.—Maslowski reports a case of traumatic injury to the brain, involving the cortical portion of the posterior division of the 3d frontal and the middle portion of the central convolutions on the left side. The bone was depressed and it was evident that a clot formed subdurally. This injury was followed by paralysis of the muscles of the face and arms and aphasia from which the patient recovered without any surgical intervention. [A. R.]

4.—Marowski reports a rare case of hysteria in a girl, 19 years old, of a neurotic disposition. The mother was an alcoholic. The patient as well as the other members of the family suffered from periodical epistaxis. Having received news of the death of her father, she fainted and upon recovery discovered a numbness and weakness in her legs and spine, rendering locomotion and standing difficult. This gradually increased and in a few days she was neither able to stand, walk or sit. There was complete paralysis of both legs, loss of muscular sense, anesthesia in the region of the legs, gluteal muscles, perineum, around the anus, external genitals and sternum. In other parts of the body there were hyperesthetic areas. Both the sphincters of the rectum and bladder were paralyzed and defecation and urination were involuntary. The clinical picture was that of transverse myelitis. By means of hypnotic suggestion the diagnosis of hysteria was established and the patient finally cured. [A. R.]

Society Reports.

MEETING OF THE NEW YORK MEDICAL ASSOCIATION.

(Continued from Page 733).

Dr. Wood referred to a differentiation between cardiac manifestations of arteriosclerosis in patients, first, who have cardiac disease, and secondly, in those who have primary cardiac disease, valvular disease. Some young men have a form of arterio-capillary fibrosis. That is an advancing disease. Cases of 26 and 36 years have been observed without any evidence of primary interstitial nephritis. These cases do not seem to yield to the remedies that control the other cases spoken of, and their causation will be found to differ from the causation of arterial disease spoken of to-day. These persons are under high tension and continued strain; in fact, they *actually sleep under high pressure*. Diet and prophylaxis are important to observe. Coffee irritates and contracts the arterioles, throwing the blood back into the larger arteries. The Nauheim treatment was mentioned.

Dr. Alleman did not agree with Dr. Rochester in condemning digitalis. While it may not be so appropriate in the first and second stages, yet it is good in the terminal stage, or digitalis combined with mercury. "Strenuous life," as was referred to in the President's case, has a great deal to do with this disease. The doctor did not believe in these cases as being neurasthenic, but true arteriosclerosis.

Dr. Rochester, in closing, said that he had very little use for digitalis in arteriosclerosis where there is accompanying heart disease, on these grounds: "We have a condition in arteriosclerosis in which, by the use of digitalis, the greater strain is thrown on the heart by the action of the vessel walls. Where the heart is dilated, digitalis is useful; it is useful for a temporary time. But what do you do? You give that heart a rest and digitalis does not do that. You should put your patients in bed and keep them there, giving them that physiological rest and the heart will quiet down. Digitalis is absolutely wrong in those cases. Given regularly, 1, 2 or 3 minims every night gives a wrong sense of strength to the individual, when he ought to be in bed."

Dr. Sturgis asked Dr. Rochester what kind of cactus he used, to which he replied that there is only one good preparation of cactus, and that is Merrill's fluid extract of cactus. Dr. Rochester believed that cactus was particularly useful, as it did not have such a deleterious effect upon the arterioles as does digitalis. Cactus should not be used continuously. Nux vomica improves the heart-tone and helps better than anything else. Dr. Rochester did not believe that heredity played so great a part in the pathogenesis of the disease, but rather the *mode of life*. He had three cases in which the pain was epigastric, where there was discovered to exist serious disease of the myocardium, and of the coronary artery.

Dr. Le Fevre used small doses of digitalis for nutrition of the heart.

Blood Examination from the Standpoint of the General Practitioner. Dr. Frank W. Higgins, Cortland.

The doctor referred to the technic and instruments necessary. Specific gravity has an important bearing to the disease. He laid stress on the importance of microscopical examinations in certain diseased conditions and the uses of the urinometer. Routine examinations of the blood may be profitably made by the general practitioner.

Dr. Richard C. Cabot, Boston, said that every one could study the blood and make it useful in his general practice. He spoke of the iodophilic reaction of the blood and recommended the hemoglobinometer, which, he said, was accurate for any clinical purposes. He pays more attention to the hemoglobin than to the specific gravity. It is false to suppose that leukocytes mean pus. They rather represent a toxemia, produced by a purulent condition or uremia. It is not a specific indication of pus.

Conservative Surgery in the Treatment of Tubercular Glands of the Neck. Dr. Parker Syme, New York. The doctor did not believe that radical surgery in this tubercular

affection was the best. Operations are not well borne by tubercular patients, they should not be performed, except where absolutely necessary, and then made as light as possible. Operation produces shock to the patient's physical strength and lowers the vital powers. Complete removal should only be practiced where the disease has resisted all other treatment. Systemic infection from tubercular adenitis is rare. When the glands are broken down, they should be curetted. When a gland remains large for some time and does not decrease in size, it should be removed. The author, however, does recommend removal when the case is neglected and there is evident degeneration of the glands. Patients should live an out-of-door life, never be over-fatigued, much time spent in the actual sun, should sleep in a well-ventilated room, with windows wide open, but with a warm room to dress in. He likewise advocated the cold bath and a nutritious diet. Drugs are seldom necessary. If the patient is anemic, iron should be given. Hygienic conditions and the best environments with local treatment should be observed.

Dr. John Allan Wyeth, who is president of the American Medical Association and of the New York State Medical Association, read his address, entitled: **Comments on Some New Surgical Methods.**

His paper was divided into four parts: (1) Anesthesia of the lower half of the body by injections of hydrochlorate of cocaine into the subarachnoid space of the spinal cord. (2) The obliteration of bloodvessels by injection. (3) Prostatectomy. (4) The effect of removal of the ovaries upon carcinoma of the breast.

1. The doctor gave to Dr. August Bier, of Kiel, Germany, the credit for the new method of spinal anesthesia; also referred to Dr. J. Leonard Corning's method of employing cocaine as a general anesthetic. The author believed that the new method of anesthetizing would find a permanent place in surgical practice. The doctor cautioned against its indiscriminate employment, the importance of making a proper selection of cases, and of commencing with the minimum quantity, 1/5 of a grain. It is especially adapted to patients afflicted with certain forms of nephritis. He recommended the technique as given by Dr. Wm. R. Stone, of New York, who suggests an aseptic aqueous solution of 1/5 of a grain of hydrochlorate of cocaine to be used at one injection. The spinous process of the 4th lumbar vertebra is accurately located and the point of the needle introduced just outside of the spine between the 4th and 5th lumbar vertebrae, at an angle of about 30 degrees, from without inward, and from below upward. The patient should be in the exaggerated bicycle position, or Sim's position, with the back bent forward as far as possible. In his own practice, the author sterilizes the skin for 2 or 3 inches around the point of puncture, and cocaineizes the integument and the deeper tissues entirely down to the lamina with 2% or 4% solution. The skin is punctured with a bistoury so that the needle may be carried directly into the muscular substance, avoiding even the smaller danger of carrying the *staphylococcus epidermidis albus* into the subarachnoid space.

2. Dr. Wyeth had observed the results of Professor Darwin's operations, where he excised the external carotid arteries and their branches for the purpose of cutting off the blood supply to inoperable tumors in the nasopharynx. In January, 1901, Dr. Wyeth made experiments on dogs, into the iliac artery of one of which he injected pure alcohol; into another, heated liquid paraffine, which was coagulable at 108° F., into another, boiling water. In the first experiment the artery was still pervious; in the second, the vessel was occluded down to vessels of about 1/20 of an inch in diameter; in the third, there was complete arrest of circulation, and gangrene ensued. The doctor then cited operations performed, using his experiments as a basis thereto.

3. Prostatectomy. "Recent developments in the operative surgery of the prostate have done much to remove the opprobrium from the surgical art which the long and deplorably unsatisfactory treatment of obstructive prostatic hypertrophy justified. Parents are now no longer condemned to years of suffering and annoyance." The first real advance in prostatic surgery was the operation which consisted in the exposure of the prostate by a perineal incision, with the piece-meal removal by scissors, or by enucleation of the hypertrophied portions of that

organ. For the final radical procedures we are indebted to Nicol, Samuel Alexander, Eugene Fuller, Parker Synms, and others. Various techniques were then described. In conclusion Doctor Wyeth said that it is a matter of great satisfaction to note that the death rate following prostatectomy has gradually diminished, as the operation has been more thoroughly developed. "I do not hesitate to express the opinion that this operation is one of the most valuable contributions which has been made to surgery within the last decade."

4. The effect of removal of the ovaries upon carcinoma of the breast. Mr. George T. Beaston's (Glasgow) experiments of extirpating the ovaries with coincident diminution in breast cancer and ultimate disappearance were then related. Dr. Robert Abbé had likewise performed successful oophorectomies in this country, with atrophied changes in already present nodules and their final abolition. Dr. Wyeth looked very hopefully to this means of eradicating cancerous growths.

AFTERNOON SESSION, OCTOBER 23, 1901.

The Value of Bacteriological and Pathological Research in Diagnosis, Prognosis and Treatment in Practical Surgery.

Dr. Richard C. Cabot, of Boston, presented the subject of *Iodophilia*. This solution consists of iodoform 1 part, iodid of potash 3 parts, water 100 parts, and then enough gum-arabic to make a thick syrup. The doctor then reviewed the various tests of *Iodophilia* where it demonstrated the presence of certain surgical and pathological affections, appendicitis, peritonitis, empyema, etc. The doctor showed lantern-slides, giving the leukocytes, red corpuscles, etc., with their various positive and negative reactions. While the doctor did not say that the *Iodophilia* test was absolute in every case, yet its evidence was sufficiently conclusive on the whole to warrant its general use.

Clinical Laboratory in Surgical Diagnosis, was the title of a paper presented by Dr. Simon Flexner, Philadelphia. The Doctor referred to the importance of making laboratory work effective, and that the demonstration of different kinds of bacteria in surgical disease would modify our diagnosis. Making cultures of the blood, the Widal reactions, and especially the examination of the blood for parasites, as in malarial cases, are of the greatest assistance. To make a laboratory valuable and to carry out laboratory diagnosis, the necessary equipment is required. Laboratory diagnosis is most valuable when correlated with clinical diagnosis; its true purpose is to aid and supplement clinical diagnosis, to correct any methods, to connect the specific causes and effects of disease, and thus to contribute a more scientific and rational treatment.

(To be Continued).

Meeting of The Research Society, Cincinnati, O., October 17, 1901. Dr. S. P. Kramer read a paper entitled *Experimental Notes on Shock*. He showed that the effect on the circulatory and respiratory systems of irritation of a sensory nerve depended on the state of the cerebrum. The effect varies under varying degrees of anesthesia. When a sensory nerve is irritated in animals that are not anesthetized, the blood pressure rises, the cardiac rhythm and the respiration increase in frequency and amplitude. The same amount or even a greater amount of irritation under complete anesthesia is practically without effect on the circulation or respiration. With semi-anesthesia, in which the corneal reflex was present, irritation of a sensory nerve was followed by a marked fall in blood pressure—vasomotor shock. In another series of experiments, he showed that the spinal ganglion tends to inhibit or modify sensory impressions on their way to the central nervous system. Electrical irritation applied to the posterior root of a spinal nerve central to the ganglion, of such intensity as to produce the above effect on the circulation and respiration, failed to produce the effect on the same animal under the same conditions of anesthesia when applied peripheral to the ganglion. Dr. William Muhlberg fully agreed with him in regard to the difficulty of working out the pathology of shock by

experiments on the lower animals. They show only a slight tendency toward this condition, and this becomes more marked the lower down the scale of life we go. He believes that not only do the ganglia modify nerve impulses, but that this influence is most important both physiologically and pathologically. It is possible in Dr. Kramer's experiment that the ether so changed the conductivity of the ganglia-cells that ordinary impulses were no longer able to pass through them. If this is true, it throws much light on the manner in which ether causes anesthesia. But another explanation is possible. The conditions of the experiment rendered necessary the cutting of the sensory nerves peripheral to the ganglion. In so doing damage was inflicted to the neurons whose cell-bodies are in the ganglion and it is not unreasonable to suppose that this injury, by exerting a shocking influence on the cell, lowered the conductivity of the ganglion. In demonstrating before classes at college the effect on blood-pressure of stimulating the central end of the sciatic nerve, he has frequently noticed that the rise was much more marked when the electrodes were applied to the unsevered nerve, i. e., when the afferent conducting neurons had in no way been injured. The difference in the pressure was much too great to be accounted for by the local constriction in the limb resulting from stimulation of the efferent vaso-constrictors in the uncut nerve. If the assumption of neuron-cell shock is correct, it will assist in elucidating many problems in nervous pathology. As for instance, we know that transection of the spinal cord causes "shock" of that portion of the cord behind the lesion. This so-called shock is, however, not in the cord itself but in the posterior spinal ganglia, for when an attempt is made to elicit a reflex response by stimulating afferent nerves peripheral to the ganglia, no result follows, while stimulation of afferent nerves between the cord and the ganglia causes normal responses. In this case, the posterior spinal ganglion cells have, in all probability, been shocked by the section of their protoplasmic prolongations which run up the cord in the columns of Goll, Burdach, etc. Dr. M. L. Heldingsfeld said that it would be easy to determine whether or not this inhibitory influence attributed to these ganglia was due to any inherent property or to shock following injury, by performing the same experiments on animals with uncut sensory nerves. He then presented a paper on *generalized vaccination eruption*, (*vaccinia généralisée*), reporting a case in a child of five years. The eruption appeared three weeks after vaccination, and spread in the form of vesicles and bullae, in successive crops, over the entire body, beginning on the ankles and wrists. The duration of the eruption was about three months. His deductions were: that the disease bears the same relation to vaccination as vaccination does to smallpox; that some of the cases are due to direct inoculation of the virus by means of the finger nails, garments, etc.; that others are due to misdirected virus through the lymph and blood circulation; others are the expression of the reaction of the system against the general intoxication from vaccination; all cases require a special idiosyncrasy on the part of the patient; and that the blood examination reveals a very low eosinophilia, which moves the affection from the general bullous eruptions, while the leukocytosis and other changes bring the disease among the acute infections. Dr. Friedlander, who had made the blood examination in the case reported, found a moderate leukocytosis and this differential count: polymorphonuclear neutrophils 81%, small lymphocytes 9%, large lymphocytes 6%, and eosinophiles 5%. The small number of eosinophiles he considered to be important because of the question of diagnosis. In other bullous eruptions, especially in pemphigus, which this case resembled, one would expect to find marked eosinophilia. The blood count would therefore seem to rule out this condition. Another point of interest was the relative increase in the polymorphonuclear neutrophils, to 81%, as in the infectious diseases. The explanation of the case that Dr. Heldingsfeld has given possibly explains this part of the blood finding. Dr. Kramer suggested that the case was in reality smallpox. Dr. Heldingsfeld concurred with Dr. Kramer, in as much as variola is the same as vaccination, modified only in degree.

THE EXECUTION OF CZOLCOSZ.

By CARLOS F. MacDONALD, A. M., M. D.,

of New York.

The execution by electricity of Leon F. Czolgosz, which took place in the State Prison at Auburn, New York, on the morning of October 29, 1901, terminated the earthly existence of the most monstrous magnicide of the age. Every precaution was taken by the Warden of the Prison, under whose immediate supervision and direction the execution was conducted, to minimize the opportunity for notoriety, as well as to insure that the taking off of the prisoner should be effected in an orderly and dignified manner.

The official witnesses, consisting of prominent New York State officials, several physicians, representatives of the respective press associations and two official physicians,—Doctor John Gerin, Prison physician, and myself,—having been assembled in the execution room and received the usual admonition from the Warden as to the maintenance of order and quiet during the execution, the prisoner was conducted to the room by a guard on either side a few minutes after 7 A. M. As he entered the room, his head was erect and his manner self-possessed and defiant. Immediately after being placed in the fatal chair the binding straps were quickly adjusted on his arms, legs and body, the head and leg electrodes were placed *in situ* and connected with the wire which was to transmit the lethal current through his body. The criminal offered no resistance whatever, but during the preparations addressed himself to the witnesses in the following significant language: "I killed the President because he was the enemy of the good people—the good working people. I am not sorry for my crime. I am sorry I could not see my father." At this juncture, everything being in readiness, the Warden gave the signal to the official electrician in charge of the switch, who immediately turned the lever which closed the circuit and shot the deadly current through the criminal's body. The instant the contact was made, the body was thrown into a state of extreme rigidity, every fibre of the entire muscular system being in a marked condition of tonic spasm. At the same time consciousness, sensation and motion were apparently absolutely abolished.

Czolgosz was pronounced dead by the attending physicians and several of the other physicians present, in four minutes from the time he entered the execution room, one minute of which period was occupied in the preliminary preparations, one minute and five seconds in the electrical contacts and the remainder of the time in examinations by the physicians to determine the fact of death.

Two electrical contacts were made occupying in all one minute and five seconds. In the first contact the electro-motive pressure was maintained at 1800 volts for 7 seconds, then reduced to 300 volts

for 23 seconds, increased to 1800 volts for 4 seconds, and again reduced to 300 volts for 26 seconds, when it was broken. The second contact was maintained at 1800 volts for 5 seconds. That conscious life was absolutely destroyed the instant the first contact was made, was conceded by all of the witnesses.

Immediately after the execution, the lay witnesses having departed, an autopsy was made by Dr. Edward A. Spitzka, of New York, under the direction and supervision of the official physicians and in the presence of several of the visiting physicians who were invited to attend. The autopsy occupied more than three hours and embraced a careful examination of all the bodily organs, including the brain, all of which were found to be in a perfectly normal state,—a conclusion which was concurred in by all the physicians present.

In compliance with the expressed wish of the relatives of the criminal, the Superintendent of State Prisons, who was present, and the Warden, declined positively to allow any portion of the body to be removed from the prison. Consequently, and regrettably, it was impossible to retain honorable possession of any portion of the brain for future examination and study. Accurate drawings, however, and detailed anatomical descriptions of the brain were made by Dr. Spitzka for subsequent study and report. A careful, naked-eye examination of the brain in all of its parts was also made and full notes taken thereof. The organ and its appendages appeared to be absolutely healthy and free from any abnormality whatever, thus corroborating the opinion of the mental experts who had examined the criminal during life, namely, that he was perfectly sane.

Respecting the question of Czolgosz's mental condition, it appears that all of the mental experts at his trial, on either side, namely, Doctors Putnam, Fowler and Crego for the people, and Arthur W. Hurd and myself for the defence, after repeated examinations, concurred in the opinion that he was sane. A final examination of the criminal, with reference to his mental condition, was made by Dr. Gerin and myself at the Auburn Prison on the evening before his execution with entirely negative result. In fact, none of these examinations disclosed, in the opinion of any of the experts, the slightest evidence of mental disease or mental degeneracy. On the contrary, he was regarded as exceptionally intelligent for one in his walk of life.

Furthermore, this conclusion was fully corroborated by his manner, appearance and declarations in the execution room as well as by the post-mortem findings. Moreover, Czolgosz's bearing, conduct and declarations from the time he murdered the President down to that of his execution have been entirely consistent with the teachings and the creed of Anarchism and stamp him as an Anarchist of the deepest dye.

OFFICIAL REPORT OF THE EXPERTS FOR THE PEOPLE IN THE CASE OF THE PEOPLE VS—LEON F. CZOLGOSZ.

By JOSEPH FOWLER, M. D.,
of Buffalo, N. Y.

FLOYD S. CREGO, M. D.,

Professor of Insanity and Brain Diseases in University
of Buffalo.

and JAMES W. PUTNAM, M. D.,

Professor of Nervous Diseases in University of Buffalo,
N. Y.

September 28, 1901.

Hon. Thomas Penney,

District Attorney, Erie County, N. Y.

Sir:

Complying with your request to examine into the mental condition of Leon F. Czolgosz and report to you the result of our findings, we respectfully submit the following:

In conducting the examinations of the prisoner, we eliminated all bias and personal revenge, which so revolting a crime might suggest, to reach a just conclusion as to his mental state.

The early opportunity afforded us to examine Czolgosz, such examinations beginning but a few hours after the commission of the crime, while he was still uninformed of the fate of his victim, or had time to meditate upon the enormity of his act, aided us materially in our work.

As will be seen from our report, the prisoner answered questions unhesitatingly during the first three examinations.

After this he became more cautious and less communicative when interrogated as to the crime. From September 10th until after his trial he never volunteered any information to the examiners, and answered only in monosyllables, except to his guards, to whom he talked freely.

Leon F. Czolgosz is 28 years old, born of Polish parents, at Detroit, Mich., single, five feet 7 5/8 inches high, weighs 136 pounds, general appearance that of a person in good health, complexion fair, pulse and temperature normal, tongue clean, skin moist and in excellent condition. Pupils normal and react to light, reflexes normal, never had serious illness. He had a common school education, reads and writes well. Does not drink to excess, although drinks beer about every day, uses tobacco moderately, eats well, bowels regular. Shape of his head normal as shown by the diagram obtained by General Bull, Superintendent of Police, with a hatter's impress.

The face is symmetrical, one eyebrow was apparently asymmetrical, and elevated, as it had been cut some years ago by a wire while he was working in a wire factory. There was also a small scar on left cheek due to slight injury while at work.

At our first interview, held September 7th, he made the following statements during a lengthy examination by all three examiners: "I don't believe in the Republican form of government, and I don't believe we should have any rulers. It is right to kill them. I had that idea when I shot the President, and that is why I was there. I planned killing the President three or four days ago after I came to Buffalo. Something I read in the Free Society suggested the idea. I thought it would be a good thing for the country to kill the President. When I got to the grounds I waited for the President to go into the Temple. I did not see him go in, but someone told me he had gone in. My gun was in my right pocket with a handkerchief over it. I put my hand in my pocket after I got in the door; took out my gun, and wrapped the handkerchief over my hand. I carried it that way in the row until I got to the President; no one saw me do it. I did not shake hands with him. When I shot him, I fully intended to kill him. I shot twice. I don't know if I would have shot again. I did not want to shoot him at the Falls; it was my plan from the beginning to shoot him at the Temple. I read in the paper that he would have a public reception. I know other men who believe what I do, that it would be a good thing to kill the President and to have no rulers. I have heard that at the meetings in public halls. I heard quite a lot of people talk like that. Emma Goldman was the last one I heard. She said she did not believe in government nor in rulers. She

said a good deal more. I don't remember all she said. My family does not believe as I do. I paid \$4.50 for my gun. After I shot twice they knocked me down and trampled on me. Somebody hit me in the face. I said to the officer that brought me down "I done my duty." I don't believe in voting; it is against my principles. I am an Anarchist. I don't believe in marriage. I believe in free love. I fully understood what I was doing when I shot the President. I realized that I was sacrificing my life. I am willing to take the consequences. I have always been a good worker. I worked in a wire mill, and could always do as much work as the next man. I saved three or four hundred dollars in five or six years. I know what will happen to me,—if the President dies I will be hung. I want to say to be published—"I killed President McKinley because I done my duty." I don't believe in one man having so much service, and another man should have none."

On the second day's examination we covered about the same ground as on the previous day in order to test his memory and to compare his statements. We found his memory perfect and his statements almost identical. On this examination we gained some further information, that for many months he had been an ardent student of the false doctrines of Anarchy; that he had attended many circles where these subjects were discussed. He related how a friend of his had broken away from the circle because he had changed his views and did not agree with him and the others in their radical ideas of government. He had heard Emma Goldman lecture, and had also heard lectures on free love by an exponent of that doctrine. He had left the Church five years ago because, as he said, "he didn't like their style." He had attended a meeting of Anarchists about six weeks ago, and also in July. Had met a man in Chicago about ten days ago who was an Anarchist, and had talked with him. One Friday before the commission of this crime, he had spent in Cleveland, leaving Buffalo, where he had been for two or three weeks, and going to Cleveland. Said he had no particular business in Cleveland. "Just went there to look around and buy a paper."

The circle he belonged to had no name. They called themselves Anarchists. At every meeting they elected a Chairman and usually it was one man (mentions name). "He was a sort of spokesman for the crowd. This friend of mine who left the circle, I don't think much of. I don't like a man who changes around like he did. I like a man to have a fixed purpose, and one who sticks to his belief. ... this circle we discussed Presidents, and that they were no good, but didn't say they must be killed; just said they were no good." During this examination the prisoner was very indignant because his clothing was soiled at the time of his arrest, and he had not had an opportunity to care for his clothing and person as he wished. He refused to demonstrate again how he covered his weapon with a handkerchief because his was soiled and bloody. When given a clean one he showed at once the method of concealing the weapon, and how he held it. His desire to keep himself tidy, demonstrated that he was not careless in dress and appearance, as are most insane persons. He requested clean clothing, and as he had a small amount of money, a shirt and two handkerchiefs were purchased for him with it. When they were brought in the change was shown him. He instantly turned to the officer and said, "How is that? Don't I get more change? The cost of the articles was told him, and he said, "Oh, that's all right then." Said he would have slept well last night but for the noise of people walking about. He had heard several drunken people brought into the station at night. Said he felt no remorse for the crime which he had committed. Said he supposed he would be punished, but every man had a chance on a trial; that perhaps he wouldn't be punished so badly after all. His pulse on this occasion was 72; temperature normal; not nervous or excited.

On September 9th we observed a marked change in his readiness to answer questions. Many of the questions asked he refused to answer. He denied that he had killed the President or that he meant to kill him. Seemed more on his guard, and refused to admit that he shot the President. He persisted in this course until nearly the close of the interview, and until we told him that it was too late for him to deny statements that he had made to us. He then said, "I am glad I did it."

At all subsequent interviews he declined to discuss the

crime in any of its details with us, but would talk about his general condition, his meals, his sleep, and how much he walked in the corridor of the jail, or upon any other subject not relating to the crime. From the daily reports filed with us we note that he talked freely; that his appetite was good; that he enjoyed his walks which he took in the corridor of the jail. He told his guards he would not talk with his lawyers because he did not believe in them, and did not want them.

In conclusion, as a result of the frequent examinations of Czolgosz, of the reports of his watchers during his confinement in the jail, of his behavior in court during the trial, and at the time he received his sentence, we conclude that he was sane at the time he planned the murder, when he shot the President, and when he was on trial. We come to this conclusion from the history of his life as it came from him. He had been sober, industrious, and law-abiding; till he was twenty-one years of age, he was as others in his class, a believer in the Government of this country and of the religion of his fathers. After he cast his first vote he made the acquaintance of Anarchistic leaders who invited him to their meetings. He was a good listener, and in a short time he adopted their theories. He was consistent in his adherence to Anarchy. He did not believe in Government, therefore he refused to vote. He did not believe in marriage, because he did not believe in law. He killed the President because he was a ruler, and Czolgosz believed as he was taught that all rulers were tyrants; that to kill a ruler would benefit the people. He refused a lawyer because he did not believe in law, lawyers or Courts.

We come to the conclusion that in the holding of these views Czolgosz was sane, because these opinions were formed gradually under the influence of Anarchistic leaders and propagandists. In Czolgosz they found a willing and intelligent tool; one who had the courage of his convictions, regardless of personal consequences. We believe that his statement, "I killed the President because I done my duty," was not the expression of an insane delusion for several reasons. The most careful questioning failed to discover any hallucinations of sight or hearing. He had received no special command; he did not believe he had been especially chosen to do the deed. He always spoke of his motive for the crime as duty; he always referred to the Anarchists' belief that the killing of rulers was a duty. He never claimed the idea of killing the President was original with him, but the method of accomplishing his purpose was his, and that he did it alone. He is not a case of paranoia, because he has not systematized delusions reverting to self, and because he is in exceptionally good condition, and has an unbroken record of good health. His capacity for labor has always been good, and equal to that of his fellows. These facts all tend to prove that the man has an unimpaired mind. He has false beliefs, the result of false teaching and not the result of disease. He is not to be classed as a degenerate, because we do not find the stigmata of degeneration; his skull is symmetrical; his ears do not protrude, nor are they of abnormal size, and his palate not highly arched. Psychically he has not a history of cruelty, or of perverted tastes and habits. He is the product of Anarchy, sane and responsible.

Respectfully,

Signed,

JOSEPH FOWLER, M. D.
FLOYD S. CREGO, M. D.,
JAMES W. PUTNAM, M. D.

LA PRESSE MEDICALE.

July 10, 1901. (No. 55).

1. New Experience in Smallpox.
HENRI ROGER and EMILE WEILL.
2. The Treatment of Injuries of the Sinuses of the Dura.
GEORGE LUYSS.

1.—Roger and Weill give in detail their latest experiments upon rabbits with the pus of smallpox. An eruption developed, about the point of inoculation, consisting of a few papules, as in new-born infants. Thus their latest experiments confirm their earlier ones, in showing the resemblance between small-pox in the rabbit and young infants. [M. O.]

2.—The treatment of suspected injury of the sinuses of the dura mater is immediate operation. The skull must be

trephined at the point of traumatism immediately. The hemorrhage can be stopped by digital compression, packing, with gauze or with catgut, permanent pressure, ligation, or lateral ligation. But one of two grave accidents may occur, sinus-thrombosis or the entrance of air into the sinus, with death following at once. [M. O.]

July 13, 1901. (No. 56).

1. Congenital Lymphadenoma in the New-born.
E. BONNAIRE and DECLOUX.
2. The Elimination of the Pigment in Pigmented Diabetes.
RABÉ.
3. The Treatment of Urinary Infiltration, Abscess, and Fistula. H. HARTMANN.

1.—Bonnaire and Decloux report the case of an infant admitted to the hospital when two days old. It looked hereditarily syphilitic, had a huge abdomen, ascites, and edema of the legs. The liver was found enlarged and regular on palpation. A large smooth tumor filled the left hypochondrium. It was firm, and suggested a hypertrophied spleen. The diagnosis made was congenital syphilis. Pemphigus, cyanosis, fever, bronchopneumonia, and death followed. The autopsy showed that the tumor filling the left hypochondrium was a lymphadenoma of the left suprarenal capsule. The liver, pancreas, right suprarenal, and lungs were filled with lymphatic tissue, and enlarged lymph-glands existed throughout the body. They believe that lymphadenoma is probably a malignant tumor.

[M. O.]

2.—In hypertrophic cirrhosis of the liver with pigmentation of the skin, of diabetic origin, the red blood corpuscles are dissolved, and the hemoglobin is set free in the blood, whence follows the pigmentation. Rabé discusses the elimination of this pigment, hemosiderin. He reports a case, in a man of 47, of associated diabetes mellitus and Addison's disease, which ended fatally. Full autopsy notes are given, which show the universal distribution of the pigment. After a discussion of the subject, Rabé concludes that the epithelium lining the excretory ducts of the liver, pancreas, salivary glands, etc., may become impregnated with this iron pigment; that this may also occur in the trachea, bronchi and alveoli; that the pulmonary capillaries may contain pigment emboli; and that these conditions show the modes of elimination of the pigment. Thus, the glandular cells have two ways of eliminating this pigment, by the excretory ducts of the gland, and by the lymphatic or venous channels through the lungs. Here the fine particles fall into the alveoli, and are exhaled. The rest of the hemosiderin reaches the circulation, and is excreted through the kidneys. [M. O.]

3.—Hartmann states that the point of rupture of the urethra in urinary infiltration is always along the side of the urethra, just in front of the median aponeurosis. The urine reaches the inferior perineal cavity, and infiltrates the abdominal wall, the penis, and the scrotum. If this urine is septic, it forms a urinary abscess. The first treatment indicated is numerous small incisions to evacuate the urine. Then a perineal incision should be made, above the anus, to the urethra, and a drainage tube left in place. For acute urinary abscess, Hartmann advises simple incision and drainage; when the abscess persists, the entire abscess sac should be extirpated. The treatment of urinary fistula is the same. Operation for the cause of these conditions should be left until all chance of sepsis has passed.

[M. O.]

A Case of Separation of the Mucous Membrane of the Esophagus following Poisoning with Caustic Alkali.—Zembrzshuski (*Gazeta lekarska*, March 17, 1901; *Vratch*, Vol. XXII, No. 18) reports the case of a girl of 18 who took some caustic alkali with suicidal intent. The amount taken was not enough to have the desired effect but was sufficiently large to disable her from swallowing even liquid food, the ingestion of which caused vomiting. On the fourth day the vomited matter contained a piece of what she called "intestine," 18 cm. long, which on microscopical examination proved to be the entire mucous membrane of the esophagus. By the introduction of sounds of various sizes contraction was prevented and the patient was soon able to swallow liquid food. [A. R.]

THE ULTIMATE RESULTS OF OPERATION FOR
CANCER OF THE UTERUS.By CHARLES P. NOBLE, M. D.,
of Philadelphia.

Surgeon-in-Chief, Kensington Hospital for Women, Philadelphia.

During the century which has just closed surgery has made marvelous progress in many directions, and in no department is this more true than in that of gynecology. Methods of cure have been discovered and perfected for ovarian tumors, fibroid tumors, vesical and intestinal fistulae, lacerations of the pelvic soft parts and inflammatory diseases of the uterine appendages. Unhappily this brilliant record has not extended to the cure of cancer of the uterus. The status of the treatment of cancer is much better and more hopeful than it was a century ago, for we are now able to cure a certain percentage of cases. Nevertheless, for the greater proportion of cases of cancer of the uterus surgery is still helpless. As medical science has led to the prevention or control of the great epidemics which formerly decimated the race, and as now the causation of tuberculosis is known and its curative treatment in much better understood, the greatest problem which confronts the medical world in the twentieth century is to learn the causation, prevention, or cure of cancer.

It is my purpose in this communication to review briefly the present status of the treatment of cancer of the uterus, and to report my own experience in this connection. The question of the results of treatment of cancer of the uterus has recently been widely discussed not only in our country, but also in France and Germany. The following is a brief summary of some of the views which have been expressed by prominent men:

Richelot (Richelot, L. Gustave, *Sur le Traitement du Cancer Uterin par l'Hysterectomie Abdominale*, Congrès Français de Chirurgie, Paris, 1899,) after carefully studying all his own cases and those of other surgeons concludes that vaginal hysterectomy in cases of cancer of the uterus, in which the organ remains mobile and the disease is apparently sharply circumscribed, has a mortality of almost zero, and at least ten per cent. of permanent cures.

Winter (Winter, G. Genügt die vaginale Uterus-exstirpation als radicale Krebsoperation? *Zeits. f. Geb. u. Gyn.*, Bd. xliii, S. 509) states that at the Berlin Clinic, of 300 cases of cancer of the cervix operated upon before 1892, 30 per cent. were cured—that is, were free from recurrence at the end of five years. Of 30 cases of cancer of the corpus, 53 per cent. were cured. Combining all cancers of the uterus, 33 per cent. of cures were obtained. Eighty-five of these cases have remained free from recurrence from five to fourteen years. In Berlin up to 1892 28.7 per cent. of all cancers of the uterus presenting themselves were operated upon by vaginal hysterectomy. Of these 33 per cent. were cured (free from recurrence at the end of five years). This represents 9.6 per cent. of the total number of cases including the inoperable cases. In the last few years in Berlin 48 per cent. of the cases have been

operable. If the results of operation in recent years prove as good as prior to 1892, about 15 to 20 per cent. of all cases will be cured. This improvement in results has been made possible by educating the Berlin public to a recognition of the necessity for an early diagnosis.

Olshausen (Olshausen, R. Discussion on Cancer of the Uterus and Its Surgical Treatment, Thirtieth Congress of the German Surgical Society, Berlin, 1901; *British Gyn. Jour.*, 1901, May, p. 13) usually employs vaginal hysterectomy for cancer of the uterus. Formerly he operated upon about 30 per cent. of the cases presenting themselves. He now operates upon about 50 per cent. Recurrence is most often met with before the third year, it is not uncommon between the third and fifth years, but is very rare later. He has met with one recurrence at the end of twelve years. Operating upon 50 per cent. of the cases that present themselves in his clinic, he finds that 47 per cent. are alive five years after the operation, and 18 per cent. are free from recurrence at that date. Accepting five years as a standard of cure, this would give 18 per cent. as permanent cures to be obtained by vaginal hysterectomy.

Waldstein (Waldstein, Edmund. Ueber die Erfolge der operativen Behandlung des Gebärmutterkrebses, *Archiv. f. Gyn.*, Bd. 61, H. 1) in a study of 274* cases of cancer of the uterus, operated upon by Professor Schauta by vaginal hysterectomy, in the clinics at Innsbruck, Prague and Vienna, up until January, 1899, including also Schauta's cases operated upon in private practice, gives the following results: (reports were received from 164 cases) At the end of one year, in cases in which the cancer was localized in the uterus, 5.7 per cent. had died; of those in which the cancer had extended to the glands, 42 per cent. had died. At the end of the second year, of the localized cases, 20.8 per cent. had died; of the cases involving the glands, 60 per cent. had died. At the end of six years, of the localized cases (42 cases, 24 deaths), 57.1 per cent. had died; of the cases having glandular involvement (62 cases, 54 deaths), 87.1 per cent. had died. Or, to express the matter positively, at the end of six years, in the favorable cases of cancer, 42.9 per cent. were alive, and in the cases having glandular involvement at the time of the operation, 12.9 per cent. were alive. He compares these results with those of other surgeons. At the end of five years Olshausen's statistics show in 188 hysterectomies for cancer of the cervix, 51 cases were traced, of which 17.6 per cent. were cured; in 26 cases of cancer of the corpus, 6 cases were traced, of which 66.7 per cent. were cured. Kaltenbach, in 77 cases of cancer of the cervix, 36 cases were traced, of which 13.9 per cent. were cured. Fritsch, in 65 cases of cancer of the uterus, 11 cases were traced, of which 36 per cent. were cured. Leopold, in 104 cases of cancer of the uterus, 47 cases were traced, of which 53.2 per cent. were cured. Schauta, in 154 cases of cancer of the uterus, 113 cases were traced, of which 31.5 per cent. were cured.

Pfannenstiel (Pfannenstiel, J. Ueber die Heiler-

* Schauta operated upon about 11 per cent. of the cases of cancer presenting themselves.

folge bei Krebs der Gebärmutter, *Centralb. f. Gyn.*, 1901, No. 15) reports that of the cases presenting themselves in the Breslau Clinic, 19.5 per cent. have been operated upon by vaginal hysterectomy. At the end of five years 36.2 per cent. of those traced (47 of 116 cases) were free from recurrence, which is equivalent to 15 per cent. (17 cases) of all cases operated upon, and 7 per cent. of all cases presenting themselves in the clinic. He is an advocate of vaginal hysterectomy, and believes in abdominal hysterectomy only under definite indications.

Among German gynecologists the advocates of abdominal hysterectomy for cancer of the uterus are Freund, Wertheim, Amann and Mackenrodt. (Discussion on Cancer of the Uterus and Its Surgical Treatment, Ninth Congress of the German Gynec. Soc., Giessen, 1901, May; *British Gyn. Jour.*, 1901, August, 81). One hundred and thirty-four radical abdominal operations are reported, with a primary mortality of 24.6 per cent. Schauta and Winter have each had one fatal case, and Wertheim two, from necroses of both ureters. The advocates of abdominal hysterectomy claim that the ultimate results should be much better than from vaginal hysterectomy, because of their ability to remove glands and to remove the parametria along with the uterus, but as yet sufficient time has not elapsed for them to show by statistics that this contention is valid.

Wertheim (Discussion on Cancer of the Uterus and its Surgical Treatment, Thirtieth Congress of the German Surgical Society, Berlin, 1901; *British Gyn. Jour.*, 1901, May, p. 14) states that for the last two years and a half he has invariably operated by the abdomen, and removed the ganglia, believing that the best method to augment the chances of a radical cure. He has treated in this way fifty cases, but they are too recent to found any definite conclusions upon them. So far he has not met with any recurrence. The mortality has been high. In the first thirty operations there were eleven deaths; in the following twenty operations three deaths. Having had two deaths from necroses of the ureters, he no longer denudes these so thoroughly. The removed ganglia were in all cases submitted to minute examination, and in eighteen they were found to be cancerous. He attaches greater importance to the extirpation of the broad ligament than to that of the ganglia, because it is in the parametria that recurrence most frequently takes place.

Jacobs, of Brussels (Jacobs, C. 1906 Laparotomies, *Bulletin de Gynecologie et d'Obstetrique*, No. 3, Juin, 1899) is an ardent advocate of abdominal hysterectomy for cancer, on the ground that having performed eighty-two vaginal hysterectomies for cancer, without a single death from the operation, in all of the patients recurrence took place a year after operation, and that at this time not a single patient is living. His cases operated upon by the abdominal route are too recent for definite conclusions, but he anticipates better results.

The status of operation for cancer of the uterus was discussed by the American Gynecological Society, Session of 1901 (*Amer. Jour. Obst.*, August, 1901).

J. M. Baldy wishes to call especial attention to the difference of prognosis of operation for cancer of the cervix with that of cancer of the body of the uterus. He states that practically all cases of cancer of the cervix eventually die of the disease, and that practically all cases of cancer of the body remain well if operated upon. He claims that less than 5 per cent. of cases of cancer of the cervix are cured, no matter what line of treatment is followed, whereas 75 per cent. of cases of cancer of the corpus are permanently cured by operation.

Cyrus A. Kirkley quotes Dr. Pryor as having collected a total of 98 cases operated upon by the Rumpf-Ries-Clark operation, with a mortality of 11.2 per cent., which we may contrast with the German results of 134 cases, with a mortality of 24.6 per cent. After discussing this operation and vaginal hysterectomy for cancer, preference was given to electro-cauterization as practised by John Byrne, of Brooklyn.

Hunter Robb states that his personal experience and observation are practically in accordance with those of Dr. Baldy.

Kelly's statistics are the most carefully worked out of any American surgeon (Cullen, T. S. *Cancer of the Uterus*, pp. 683, *et seq.*). Of 61 cases of epithelioma of the cervix, operated upon at the Johns Hopkins Hospital and Dr. Kelly's private sanatorium, 13 are living and well; but of the thirteen only two have been operated upon more than five years, so that the apparent cure of 20 per cent. is actually reduced to about 3 per cent. Only four cases have been operated upon more than three years; the remaining nine are more recent. Of twelve cases of hysterectomy for adenocarcinoma of the cervix, only two are still living. These may be considered cured, as one has been operated upon five years and three months, the other four years and seven months—18 per cent. of cures. Of 30 hysterectomies for adenocarcinoma of the uterus, 20 cases are free from recurrence; but of these only four are of over five years standing; eight of more than three years standing. Thus of the cases of carcinoma of the body it may be considered that 13 per cent. have been cured. In this report, of a total of 103 cases of hysterectomy for cancer of the uterus, eight cases are free from recurrence five years after operation, and may be considered cured—or 7.7 per cent. It may be reasonably expected that this percentage will be increased in the future, as the majority of the cases are of less than five years standing; therefore it is probably a conservative estimate that at least 10 per cent. of these cases will be permanently cured.

This review of the recent literature concerning the status of operation for cancer of the uterus is intended to be suggestive rather than exhaustive, but it is quite evident that the following conclusions may be drawn:

1. The majority of cases of cancer of the uterus, when they consult the surgeon, are too far advanced for the hope of a radical cure. German statistics indicate that this is less true now, than it was ten years ago. This is a hopeful indication, as showing that the teaching of surgeons concerning the neces-

sity of early diagnosis and early operation for cancer is beginning to bear fruit.

2. The percentage of cases of cancer of the cervix remaining free from recurrence at the end of five years, after vaginal hysterectomy, is variously given, but it may be claimed confidently that at least 10 per cent. of the cases operated upon remain free from the disease at the end of five years and may be considered cured. Much better results are claimed by some. Jacobs is the only authority who is absolutely pessimistic. His experience that all of his patients operated upon by vaginal hysterectomy have died of recurrence, although the operative mortality was zero, is as striking as it is unique.

3. The results of hysterectomy whether vaginal or abdominal for carcinoma of the corpus uteri are much more satisfactory. Whenever this point is brought out in statistics it is evident that about 75 per cent. of the cases are permanently cured; hence, for timely operations for carcinoma of the corpus a good prognosis may confidently be given.

4. The abdominal radical hysterectomy for cancer of the uterus, involving the removal of the pelvic glands and the parametria along with the uterus, is still upon trial. Its primary mortality is probably double that of vaginal hysterectomy, and it has not been practiced long enough for permanent conclusions as to the results which may be thus secured. Theoretically it should give better results than vaginal hysterectomy, because the parametria and at least some of the lymphatic glands of the pelvis are removed. In practice this end is not always reached. Aside from theoretical considerations the most encouraging report concerning the operation is the statement of Wertheim, that after two and a half years' experience he has not met with recurrence.

My own experience in the treatment of cancer of the uterus has been far from satisfactory. This has been less true of the results obtained from operation than of the results of treatment of all the cases of cancer coming under observation. While accurate statistics are not available to determine the exact percentage of operable cases, I am satisfied that this has been much less in my own experience than the average—probably it has been less than 20 per cent. The fact that the great majority of patients are absolutely beyond the hope of cure when first seen by the surgeon is the most discouraging feature of the whole matter. So long as the cure of cancer must depend upon operation, the hope of improvement in the results of treatment must depend more upon securing early diagnosis and early operation than upon extending the limits of operation.

For the purposes of this paper I have but thirty-two cases to report, those that have recovered from either vaginal or abdominal hysterectomy for cancer.* Of these twenty-three were cases of cancer of the cervix and nine of the corpus, two of the latter being cases of syncytioma. Of the 32 cases, 11 have since died, 10 of recurrence and 1 of pneumonia. Of the 21 cases remaining, 2 cases of cancer of the cervix are known to have recurrence, 6

cases have been lost sight of, and the remaining 13 are free from recurrence at the present time. The following table gives the length of time free from recurrence:

Cancer of the Cervix.		Cancer of the Corpus.	
1	12 years.	1	9 years.
1	9 "	1	7 "
1	8 "	1	5 "
2	3 "	1	4 "
1	2 "	1	3 "
1	1½ "		
1	1 "		

Thus of the 32 patients there are 6 living and free from recurrence at the end of five years, which is equal to 18 per cent. There are nine patients living and free from recurrence at the end of three years. Two of the additional three being cases of cancer of the body of the uterus, it is a fair conclusion that between 20 and 25 per cent. of the cases have been permanently cured.

Of the nine cases of cancer of the corpus, five are accounted for in the table, one has been lost sight of, and one died of recurrence at the end of four years and five months. The remaining two cases are of syncytioma, a condition quite distinct from adeno-carcinoma of the corpus. Of the two cases the first died of recurrence, and the second was so advanced at the time of operation that the removal of the cancer was necessarily incomplete.

These results make me reasonably hopeful of the benefits to be derived from hysterectomy in cases of cancer not too far advanced; but the rapid recurrence which has taken place in the more advanced cases, together with the more important fact that the large majority of all cases seen have been inoperable, strongly support the view already referred to, that there is far more opportunity for improvement in the treatment of cancer in the direction of early diagnosis and early operation than in improvements in the operation itself.

This brings up for our consideration the early diagnosis of cancer. The great majority of cases of cancer of the uterus first come under the observation of the family physician, and therefore in this field he has not only great opportunities, but great responsibilities. It is unfortunately true that the teachings of the profession in the past concerning cancer were such as to distinctly discourage the early recognition of the disease. This is true especially in two respects: 1. The teaching that cancer is incurable. This belief is still held not only by a large proportion of the laity, but also by a not inconsiderable percentage of the profession. 2. The classical teaching concerning climacteric hemorrhages. This one fallacy does more than anything else to prevent an early diagnosis of cancer. Women as a rule believe that it is natural and to be expected that they should have irregular discharges of blood and abnormal menstruation at or about the time of the menopause, and as this period is very indefinite in their minds, when such hemorrhages take place at any time after the thirty-fifth year, women are apt to comfort themselves with the thought that nothing is wrong; hence, instead of seeking professional advice, they avoid it. It is the duty of the profession to recognize that cancer

*Eighty cases of cancer have been admitted to the Hospital for hysterectomy, curettage, etc.

is curable by radical operation if promptly resorted to. Certainly from 10 to 20 per cent. of cases of cancer of the cervix, and at least 75 per cent. of cases of cancer of the body, can be cured by timely operation. This fact should not only be recognized by the profession, but should be taught to the laity.

The falsity of the doctrine of climacteric hemorrhages should also be appreciated and taught to women. They should be made to realize that irregular discharges, whether at or between the menstrual periods, and especially subsequent to the menopause, whether bloody or not, are due to disease of the uterus. The realization of this fact would prompt them to seek instead of avoid professional advice.

The diagnosis of cancer of the uterus may be either easy or difficult. In advanced cases there is usually a history of bloody, foul discharges, and upon examination the characteristic infiltration of the cervix, with breaking down of the cancerous mass, is easily made out. Unfortunately, while diagnosis under these circumstances is easy, a cure is usually hopeless.

In early cases hemorrhage may be present or absent. The same is true of leukorrhea. Pain is almost, if not invariably, absent, and if present is accidental. The clinical diagnosis must be made by the character of the infiltration in the cervix and upon the friability of the new growth under pressure with the finger. If infiltration is not marked and friability is not present, the disease is not sufficiently advanced for a clinical diagnosis. In such cases it is necessary to remove a section of the growth for microscopic diagnosis. Cancer of the body of the uterus is much more difficult of diagnosis. The use of the curette and a microscopic study of the scrapings is almost invariably essential. In dealing with suspected cancer conservatism does not consist in temporizing until the diagnosis becomes conspicuously manifest clinically. On the contrary, in such cases the patients should be given the benefit of the special training of the gynecologist and the pathologist. This very class of early cases is that in which the best results of treatment in the future will be obtained.

The Search for the Typhoid Bacillus in Drinking Water.

—Professor A. Chantemesse believes that typhoid bacilli often exist in drinking water which is examined without the micro-organisms being discovered. He describes in full the technique of a new method of searching for typhoid bacilli, in which six liters of the suspected liquid are used. The microbes, by passing through a Chamberland filter, are collected upon it. They are then washed off in 200 g. of sterile water containing 3% peptone. By using a very complicated apparatus, the sediment is drawn off, fresh nutriment added, and all the microbes cultivated at 37° C. They are then centrifuged and decanted. They are grown upon peptone-gelatin. The colonies of colon bacilli are removed, 16 to 17 hours later. The typhoid colonies appear from 18 to 24 hours, surrounded by a clear, translucent, transparent periphery, easily distinguished from the colonies of micrococci also present. They grow upon lactose-peptone, which will ferment, proving that the bacilli are true typhoid bacilli. Chantemesse has also used this method for finding typhoid bacilli in the stools. He believes that it should be used to make frequent examinations of the sources of all drinking water, at regular intervals, so that no water from such a source will be employed after typhoid bacilli have been found in it, even before any case of typhoid fever has resulted from its use. (*La Presse Medicale*, June 5, 1901, No. 45). [M. O.]

CHRONIC ULCERATION OF THE STOMACH SIMULATING CANCEROUS DISEASE; RELATION OF A CASE OF GASTROENTEROSTOMY WITH THE MURPHY BUTTON, RECOVERY.

By JAMES F. W. ROSS, M. D.,
of Toronto, Ont.
and E. B. O'REILLY, M. D.,
of Hamilton, Ont.

In the short paper presented, an effort will be made to impress upon the profession the fact that even after the abdomen has been opened it is difficult, if not impossible, to make a differential diagnosis between chronic ulceration and cancerous disease of the stomach. Our methods of diagnosis are very faulty and insufficient. Early diagnosis in either of these conditions is as yet almost out of the question.

Fagge says, "A case in which well marked symptoms have existed for eighteen months, or longer, may generally be pronounced to be one of simple ulcer of the stomach and not a case of malignant disease. On the other hand, cancer of the stomach may, for the most part, be diagnosed whenever the characteristic tumor is discovered accompanying the usual symptoms met with in these cases. Cases of simple ulcer affecting the pylorus have now been placed on record in which this part has been so thickened and indurated that the presence of a scirrhus mass has been simulated."

Miss D. W., act. 28. From the patient's own statement it appears that she consulted a doctor regarding the condition of her stomach, with which she has been troubled for about three years. At times she felt perfectly well and then again suffered from considerable discomfort after eating food. The discomfort frequently ended in vomiting. The vomited material was very sour and had an unpleasant odor. She found that raw fruits and any acids disagreed with her. She craved for sweet things. Her skin felt dry; the bowels were constipated. She entered the training school of a hospital in April, 1899, and the gastric condition grew worse.

In August, '99, she found it necessary to go home. She was then treated until December, but without benefit, in fact she seemed to be steadily growing worse. The abdomen became distended and pains set in in the back and there was a great deal of soreness about the waist. Shortness of breath came on and she found it necessary to sit up in order to get her breath. The patient then came under the care of Dr. E. B. O'Reilly, Hamilton, Ontario, whose notes are now given.

"The patient first came under observation in December, '99. It was found that she had been, for some months, under treatment for dyspepsia. She was emaciated and complained of suffering and pain whenever food was taken. Opium had been administered to relieve the pain and the opium habit was already formed. Physical examination revealed nothing. Food was peptonized. In spite of this and the careful medication the symptoms again became aggravated.

In January, 1900, after consultation with Dr. Griffin, the patient was sent to the Hamilton Hospital. Efforts were made to prevent fermentation of the stomach contents, rectal alimentation was persevered in with considerable benefit. The pain subsided and the patient gradually gained in weight. On March 24th, '00, she was discharged from the Hospital and remained fairly well for two weeks, but, as soon as food was passed into the stomach, the symptoms again became aggravated, the pain returned and the flatulence and nausea became troublesome. Great rigidity of the right muscle was noticed. There were several profuse hemorrhages from the stomach and bowels. Exploratory incision was strongly urged. There were five severe hemorrhages in all.

In April the patient grew worse daily. About the middle of May, '00, as Dr. Ross was in town, I asked him to see

the case with me. He also advised exploratory operation. The urinalysis showed the urine to be pale in color; Sp. Gr. 1018; alkaline reaction; no sugar or albumin; slight mucoid sediment with a few pus cells."

Dr. Ross' notes are as follows: "The patient was found, in May, '00, extremely emaciated, rigidity of the right rectus muscle was noticed, and an indefinite thickening could be felt in the epigastric region. As the patient was only twenty-eight years of age, and as malignant disease of the stomach is rather rare at this period of life, there appeared to be good ground for hesitating before making an exact diagnosis. Diagnosis of ulcer of the stomach had been made when the patient was in the Hamilton Hospital in January.

The symptoms pointed to obstruction of the pyloric end of the stomach and it was not possible to say whether this obstruction was due to the presence of cancerous growth or to some other cause. The symptoms had extended over such a period of time that they pointed to the presence of an ulcer, but the thickening that could be distinctly made out led to the belief that, in all probability, malignant disease had been grafted onto the former condition of ulceration.

There was no history of cancerous disease in the family. Some dilatation of the stomach could be made out, but there was not the enormous dilatation so frequently found in cases of cancerous obstruction of the pylorus. The rhythmic muscle waves, so characteristic of pyloric obstruction, were not observed.

On the 5th of June, '00, operation was performed by Dr. Ross, assisted by Dr. White. The abdomen was opened above the umbilicus and the stomach drawn out. A large growth was found at the pyloric end. The perigastric lymphatic glands were enlarged, and the whole stomach wall looked exactly as it does in cases of cancer. The case was looked upon as hopeless and a decision was arrived at not to attempt to remove the growth but to give temporary relief by means of a gastroenterostomy.

The operation was rapidly performed by means of a large Murphy button and an anastomosis effected between the stomach and duodenum. The patient was not in a good condition, owing to the previous starvation. The operation had to be performed rapidly to prevent collapse. Great care was taken, however, notwithstanding the necessity for haste, to carefully apply supporting sutures to prevent leakage. After the operation there was not much elevation of temperature or pulse. Patient made an uninterrupted convalescence.

On the 2d of May 1901, eleven months after operation, the patient weighed 140 pounds, looked the picture of health, and was just returning to complete her training as a nurse. On examination of the abdomen no mass could be felt. The patient was not suffering from any gastric symptoms.

Fagge says further, "That even when the symptoms point clearly to the existence of serious organic disease of the stomach, there always remains the question whether this disease is a simple chronic ulcer or cancer. Between these affections the diagnosis is often perfectly easy," and he might have added that it is sometimes extremely difficult.

In the case here recorded there was no perforation with the formation of abscess cavity, such as is occasionally found to simulate cancer very closely.

An extremely interesting case is recorded by Sidney Martin and Bilton Pollard of hour-glass contraction of the stomach with pyloric stenosis. This case helps to throw considerable light on the condition under discussion. The stomach was completely divided so that there was a larger right pouch and a somewhat smaller left pouch, formed as a consequence of the constriction across from the greater to the lesser curvature about its middle. A careful examination, post mortem, showed the presence of a chronic ulcer at the hour-glass con-

striction, that apparently had excited persistent contraction of the circular muscular fibres and lead, with the formation of fibrous tissue, to permanent structure similar to those strictures of the rectum produced by small ulcers. The pyloric stenosis that was also present seemed to result from the presence of a small duodenal ulcer with perforation, and the consequent formation of a small abscess and a large amount of cicatricial tissue between the pylorus, the duodenum and the transverse colon. The symptoms in this case lasted for over a period of ten years.

In the case of Miss D. W. the stomach was drawn out and was not adherent.

In a very interesting article Moynahan says, "The induration in some cases of ulcer may be of such density that the appearance and characteristics of the malignant growth may be mimicked with remarkable intensity. In one case of my own, which I submitted to the operation of gastroenterostomy, believing the pyloric mass to be malignant and not removable, the patient gained so rapidly in health and has so stoutly maintained his improvement for a period extending over two years, that I am skeptical as to the accuracy of my diagnosis."

Thayer, Hirsch, Lindstrom, Kammerer and others have mentioned examples precisely similar, and Mayo Robson has recorded a case of pylorectomy for supposed malignant disease which, on minute examination, proved to be chronic inflammatory thickening."

In an interesting article by Satterthwaite a description of the ulcers is given. He says "A large number of gastric ulcers have rounded contour, sharply cut edges, surrounded by a zone of tough fibrous tissue. A puckering of the gastric walls about them is present and bands of fibrous tissue radiate outwards."

This variety has been called the acute. In contradistinction to this is the chronic variety which has greatly infiltrated walls and ragged, shelving edges, forming a sort of inverted cone, the apex being at the peritoneal covering of the stomach. When exposed to the eye, there can scarcely be much mistaking such an ulcer, though it might be taken for a cancer or sarcoma. A microscopic section of such a mass might be taken for a round celled sarcoma, because in both sarcoma and gastric ulcer there is a great similarity of the character of the round cells. But if the non-malignant ulcer is brought into view the peculiar excavated centre should indicate its true character."

Scatterthwaite's observation in this connection may be quite correct, but it must be difficult for a surgeon to get such a view at the time of operation, unless a very large opening is made into the stomach wall.

Symptoms.—The ordinary symptoms of ulcer of the stomach are localized pain after eating, vomiting, hematemesis or melena, or both.

Pain.—The pain at first is often only an epigastric distress. Later on it becomes of a boring character going through the back. When the stomach is empty there is little, if any, actual pain, but when filled with food there is apt to be some immediate distress, and after a couple of hours pain increases and is no doubt due to increased acidity from the

pouring out of hydrochloric acid. The patient often obtains relief after vomiting or after the food has been carried on through the pyloric end.

In many cases hematemesis is the first sign of gastric ulcer. It must be remembered that hematemesis may occasionally be fatal apart altogether from the presence of gastric ulcer or gastric cancer, in such cases arising from chronic alcoholism and cirrhosis of the liver.

Many cases of perforation of gastric ulcer are on record in which none of the symptoms of the condition were present previous to the sudden onset of the symptoms of perforation.

Dr. Soltan Fenwick thinks that anemia, with progressive emaciation and great loathing for food, with signs of subacute gastritis, are generally suggestive, at an early period, of cancer of the stomach. He says that in 100 cases of carcinoma of the stomach 60 affected the pyloric end, 30 the walls, and 10 the cardiac end. Pain was present in 90 per cent. of the cases. It was generally constant and scarcely relieved by vomiting, and was very liable to severe exacerbations. The vomiting varied a great deal with the seat of the disease. Hematemesis was usually slight and repeated melena rare. In physical examination auscultatory percussion was especially valuable.

Diagnosis.—The period of greatest frequency of ulcer is from the ages of twenty to thirty years. There can be no doubt that cancer of the stomach is met with at an early age. The age of the patient cannot, therefore, be considered as of much assistance in making a diagnosis.

In the differential diagnosis of these cases but little advance has been made, as has already been stated. All that can be said regarding the absence of hydrochloric acid is that it makes us suspicious of cancer. Hydrochloric acid is found sometimes in excess in cases of gastric ulcer. Lactic acid only appears late and as a consequence of pyloric obstruction.

The greatest aid to early diagnosis is exploratory incision. Kocher advocates a more extensive use of the exploratory incision in doubtful cases of gastric diseases. He says that he has often regretted the delay in operating, but has never regretted doing the operation itself. He considers that the indications for operation in simple ulcer are repeated hemorrhages, even if small, especially if dilatation of the stomach is present; secondly, for violent pain and for frequent vomiting when caused by retention from pyloric obstruction; thirdly, for perforation, and fourthly, for the possibility of the condition being not simple but cancerous.

It would be well to add "for the possibility of the condition being not cancerous but simple." Surely this is a more important indication for operative interference.

Guinard holds that, on two conditions, exploratory operation is justifiable: first, when there is distinct modification of gastric chemistry, especially apepsia, and the presence of lactic acid after a test meal, and, secondly, complete failure after careful dietary and medical treatment to keep up the weight of the patient's body to its normal standard, or to restore lost weight.

The indication for operation, given by some, is

that it should be performed in the absence of hydrochloric acid when lactic acid is present and when there is reduction in the amount of albumen digested.

It seems to be apparent that before long the practice will be to perform an exploratory operation in all cases of doubtful stomach affections.

Operation.—Chronic ulcers, with thickening simulating malignant disease, are cured by a simple gastroenterostomy. The removal of cancerous growths is a very formidable procedure and not a very satisfactory one. To be satisfactory it must be performed very early in the disease, before lymphatic infection has taken place.

Barling condemns the proposal to excise gastric ulcer which has not perforated.

Kuster opened the stomach in two places and applied the actual cautery to the ulcer and then performed gastroenterostomy. The performance of gastroenterostomy, without the application of the cautery, would no doubt have been sufficient to effect a cure. His operations were performed for what I have described as the acute ulcer and not for the form under consideration, chronic ulcer with tumor mass. The excision of such a mass is an unjustifiable procedure.

It would be well to attempt to cure the simple acute ulcer by plication of the stomach wall. In this way the irritation of the food would cease to be a factor, and the ulcer would be given an opportunity to heal. The operation would be an extremely simple one and would be accompanied by very little danger.

After-Results of Gastroenterostomy. After gastroenterostomy the stomach, if previously largely dilated, reduces in size in a very short time. There may be difficulty produced by a narrowing of the new orifice, but if the operation is properly performed, this is not likely to occur. As a consequence of the operation both bile and pancreatic juice must find their way into the stomach but they evidently do no harm.

Pyloric spasm is produced as a consequence of the presence of a gastric ulcer. After gastroenterostomy the hyperacidity of the stomach disappears and the ulcer heals as a consequence of the rest obtained by the organ and the cessation of the spasm.

A Case of Myelogenous Leukemia.—Triboulet and Delcoux report a case of leukemia in a man of 46. (*Bulletin et Mémoires de la Société Médicale des Hôpitaux de Paris*, May 30, 1901, No. 18). His spleen had been enlarged for about six months. There were no other symptoms at all. He was in excellent physical condition. He had had gonorrhea, and syphilis. Lately edema of the legs developed. There was edema of the penis, followed by sexual impotence since. The spleen reached the anterior superior spinous process of the ilium, passed 3 cm. to the right of the umbilicus, and up to the eighth intercostal space. Its greatest vertical diameter was 28 cm.; transversely it measured 27 cm. The mitral systolic sound seemed prolonged. In the urine was a trace of albumin. He was constipated. Blood examination revealed 2278500 erythrocytes, 514600 leukocytes, and 30% hemoglobin. There were great numbers of neutrophilic, basophilic and eosinophilic myelocytes, some nucleated erythrocytes, and mast-cells. There was intense leukocytosis, with all the characters of myelogenous leukemia. Widal and Rendu reported having seen similar cases, in the discussion which followed. [M. O.]

THE SURGERY OF PULMONARY ABSCESS, GANGRENE AND BRONCHIECTASES FOLLOWING PNEUMONIA.

By DANIEL N. EISENDRATH, A. B., M. D.,

of Chicago.

Professor of Clinical Anatomy, College of Physicians and Surgeons, Chicago.

We can divide the history of pulmonary surgery into two periods. The first begins at the time of Hippocrates, and ends about thirty years ago. The most active part began two hundred years ago, when Baglivi opened an abscess following a stab wound of the lung. A number of reports of cases of abscess treated by surgical intervention appeared during this time. The second period dates from the time that Mosler, in 1873, attempted to cure pulmonary abscesses by intraparenchymatous injections of antiseptics. Gluck, Schmidt and Biondi (1882) showed by animal experiments that extensive pneumectomies were well borne. In 1882 Bull reported 32 cases of abscess which had been healed by operation. From that time to the present the subject has received a great deal of attention and a large number of valuable monographs have appeared, as well as the reports of individual cases. The field has been extended so that it now includes the treatment of abscess, gangrene, echinococcus, neoplasms, removal of foreign bodies, actinomycosis, and the drainage of bronchiectatic and tubercular cavities. Those who deserve especial mention in this field are Park, Tuffier, Murphy, Quinke, Godlee and Runeberg. Quinke deserves great credit for calling attention to the vast number of cases of chronic pulmonary suppuration which have been benefited by operative intervention.

It would be impossible for me to take up all of the various branches of this already extensive subject, so that I have confined this paper (in order to bring out the chief points in a particularly instructive case which occurred in my practice during the past year) to the discussion of pulmonary abscess and gangrene and bronchiectases occurring after pneumonia. I have purposely excluded the consideration of cases of any of these lesions due to any other cause. This being the first effort to classify the cases according to the etiology, it has necessitated an immense amount of tedious research into the original records of cases.

In regard to the etiology, all authors agree that abscess is far more frequent than gangrene as a sequence of ordinary croupous pneumonia, but that the opposite holds true for influenza. Laennec has stated that abscess following pneumonia is very rare. Sello, in 750 cases, of fibrinous pneumonia, found abscess 11 times, or in 1.5 per cent. Aufrecht in 253 cases, found it in 2, or 1.2 per cent., or in approximately 1,000 cases, about 1.3 per cent.

In regard to the frequency of gangrene, Grisole found no cases of gangrene in 305 cases of pneumonia, and in 70 cases of gangrene which he collected he found that pneumonia preceded the gangrene only five times. A. Fränkel found that 7.5 of all cases of influenzal pneumonia terminated in gangrene. Sello, in 750 cases of croupous pneumonia, found it only three times. Aufrecht, in 1,501 cases, never observed it.

In regard to the frequency of bronchiectasis following pneumonia, there are no statistics, so far as I can learn.

The organisms concerned in abscess formation are the pneumococcus, the colon bacillus, the influenza bacillus and the Friedländer pneumonia organism. It is believed that some of these can be directly the cause of gangrene as well as abscess formation. Gangrene of the lung may be the result of aspiration of a portion of the contents of a putrid bronchiectatic cavity, as was probably the case in my own patient. Some authors have described epidemics of pulmonary gangrene in which it would seem as though there were a separate organism concerned, but there are no reliable facts in regard to this. Pulmonary gangrene following pneumonia is especially apt to occur in diabetics, alcoholics and in the insane.

With reference to the pathology, I will state briefly that abscess may be single or multiple, and that the same is true for gangrene. The latter may be circumscribed or diffuse. The walls of the cavities in the early stages are soft, but as the disease progresses they become firm, and this pathological factor is of the greatest value in determining the healing of pulmonary foci if attacked in a surgical manner in the early stages.

The bronchiectases may be divided into the cylindrical and sacculated, the former being usually in the middle and finest bronchi. The sacculated generally arise at the expense of the lung. The bronchus itself may be closed. It may join adjacent ones so as to occupy the entire lung. They are seldom associated with tuberculosis. They are accompanied quite early by deformities of the thorax, and clubbed fingers, and are frequently associated with abscesses as well as with gangrene. The great danger in pulmonary gangrene is the frequency with which it is followed by secondary cerebral abscesses, and by putrid bronchitis and catarrhal pneumonia.

Before taking up the discussion of the symptoms and diagnosis, I would like to call attention to the fact that in this paper I have followed as closely as possible the classification proposed by Quinke of acute simple abscesses, chronic simple abscesses, with or without bronchiectases, acute gangrenous abscesses and chronic putrid abscesses with bronchiectases. This seems the most logical division of the subject which has been proposed hitherto.

Symptoms.—The history of pulmonary abscess is frequently the following: A patient who has had pneumonia, for example, of the lower lobe, will have his crisis, the physical signs begin to clear up, the temperature drops, when suddenly the temperature goes up again, becomes of a remittent type, and the sputum becomes more purulent. There may be a distressing cough accompanied by the expectoration of pus in large quantities. Some elastic fibers may be present, but are rare. There are often paroxysms of coughing with expectoration of several ounces to a cupful of pus. If the abscess cavities do not communicate with a bronchus, there is but little expectoration. There is in all cases emaciation, loss of appetite and a rapid decline in strength. If the abscess becomes chronic, there may be recurrent attacks of fever, with a great deal of expectoration. Physical examination is rather disappoint-

ing; there are few cases in which there are cavity signs present, either due to an indirect manner in which the abscess communicates with the bronchus, or to its not opening into one at all. The pulmonary lesions following pneumonia are most frequently in the lower lobes, and this is of some aid. There are no typical physical signs, owing to the fact that the cavities (be they due to abscess, gangrene or bronchiectasis) may be near the surface, or quite deeply situated, and may or may not communicate with a bronchus. Dullness, decreased respiratory murmur, vocal resonance and fremitus are present in the majority of cases, but we may have bronchial breathing. The most reliable sign is the presence of rales, large moist ones, not infrequently metallic in character. Another striking feature is the variability of the physical signs, once dullness, then tympany at the same spot. A pus cavity surrounded by aerated lung tissue and not communicating with a bronchus gives no auscultatory phenomena. Clubbed fingers develop quite early, as do also pressure symptoms on the heart, liver and spleen. If, after a pneumonia, the fever either does not disappear, or begins a few days after a crisis, and the sputum and breath become fetid, and divides itself into the characteristic three layers, gangrene must be suspected. This, as Fränkel has shown, is a frequent sequel of influenza pneumonia. In the sputum of gangrene one can usually find elastic fibers. In bronchiectasis following pneumonia the sputum may be fetid at times, but the odor is not so penetrating and there are no elastic fibres. The physical signs of both gangrene and bronchiectasis are most frequently the same as those of abscess. In a patient with bronchiectasis there is usually a history of long-continued expectoration with sudden expectoration of large quantities of pus. This, however, is not characteristic, for the same may be true of chronic simple abscess. There is said to be more mucus in the sputum of a bronchiectasis, but if there are cavities in the lung tissue due to ulcerations of bronchiectases, there may be just as much pus as from a simple abscess, and if there is associated gangrene, just as much fetor as in a gangrene.

The frequency of hemoptysis in cases of gangrenous process is due to the fact that the vessels are more apt to pass freely through the cavity, owing to the more rapid destruction of tissue.

Diagnosis.—From what has just been stated, we can say that the history is of the greatest aid in making a diagnosis, especially if a pneumonia has immediately preceded the onset of abscess or gangrene symptoms. Both are frequent after influenza pneumonia. Gangrene is also quite frequent after pneumonia in alcoholics, diabetics, and in the insane. The examination of the sputum is also of great value in making a diagnosis. In abscess it is purulent, at times of a chocolate color, and occasionally contains elastic fibers. In gangrene it is more and more offensive as the case progresses. It separates on standing into three layers, and contains elastic fibers, which the sputum of putrid bronchitis, with which it may be confounded, does not.

In bronchiectasis the sputum is at first odorless, but usually becomes foul from the stagnant pus.

In abscess the cough is often very frequent, and the amount of expectoration raised each time is small, while in bronchiectasis it is large, and the cough infrequent. It is much easier to make a diagnosis of the nature of a lesion than its seat. Exploratory puncture is both dangerous and unreliable. Cases have been reported of fatal hemorrhage (Israel) following it, and there is great danger of infecting a healthy pleural cavity. It is also difficult to determine whether the pus is intra or extra-pulmonary.

There are no absolutely reliable physical signs to assist in localization of the process. The frequency of lesions in the lower lobes after pneumonia should suggest a most careful examination of these parts. If a lesion does not communicate with a bronchus, it may give rise to no physical signs. On the other hand, the focus may be deeply situated, and the intervening lung tissue obscure the physical signs. If cavity signs are present, they are of value, but not absolute. Impaired resonance varying with tympany and the presence of moist rales, especially if coarse and metallic, are perhaps the most valuable signs. The more experience one has in abscess, gangrene or bronchiectases, the more one is convinced (especially if the cases are studied at autopsy) that the physical signs are misleading. The best clinicians make mistakes in determining the seat of lesion.

In addition to localizing the focus, we must try to ascertain its extent, and whether there are foci elsewhere. It is almost impossible to differentiate an encapsulated empyema from an intra-pulmonary focus. General disturbances and fever are more characteristic of pulmonary lesions. Differentiation from tuberculosis can be made from the presence of tubercle bacilli in the sputum, and from the previous history, greater diffusion of the tuberculosis, and its greater frequency in the upper lobes. The physical signs may be the same for both.

In regard to the X-ray, much was hoped for, but the results have not been gratifying. Its value is only relative, and a shadow may be obtained in a thickened area quite distant from the actual seat. It is no certain guide to the focus, or whether there are one or several foci. Nevertheless, if it is possible, it should be used as a matter of routine, as it may be of some value. In a recent article by Tuffier, he quotes eight cases which were examined with the X-ray by him. In five of these the pictures showed a distinct shadow at the seat of the focus. In one of the cases (bronchiectases) the physical signs pointed to a cavity higher up than the shadow in the picture, but the latter proved to be correct, and he was obliged to operate at a lower point. In another case the shadow was a little higher than the focus. In three cases the radiograph was of no value. In one the shadow was in the lower, but the focus in the upper lobe. In a second a cavity the size of an orange gave no shadow. In a third the shadow of the heart obscured that of the lesion in the lung. Other authors report similar experiences, so that we may now regard it as an aid to diagnosis, but not as a final proof of the seat of the lesion.

Prognosis.—Medically treated, the prognosis of meta-pneumonic pulmonary abscess is fair only. That a certain number of cases do heal spontaneously

there can no longer be any doubt. Cases of this kind have been frequently reported. Quinke speaks of three in his own clinic; Jacobson, of Berlin, reports six cases, of which four recovered spontaneously, one was operated and recovered, and one died. But in quite a large number of these cases of simple abscess the patients continue to expectorate pus, and the condition becomes a chronic one, and is sooner or later complicated by the development of bronchiectasis. In acute gangrene following pneumonia, there are, as in simple abscess, some spontaneous recoveries, but the outlook is generally very grave, and those afflicted die soon after its onset of sepsis. In chronic non-putrid and putrid abscesses, with or without bronchiectases, the patients are doomed to a life of chronic invalidism, and gradually die of the effects of the chronic intoxication. Since the field of lung diseases has been invaded by surgeons, the effects of surgical interference have been so striking that the day will soon come when every case should be so treated. Even in acute abscess, if no improvement follows after three to four weeks of medical treatment, they should be referred to the surgeon. Especially in the cases following pneumonia is the prognosis good. In acute gangrene the cavity should be drained as soon as a diagnosis is made. In the chronic cases the prospect of recovery is not as good as in the acute, but the majority show a complete relief of symptoms, and many are cured, so as to be able to work again. The tendency to heal, either spontaneously or after operation, in acute cases is much greater than in chronic, owing to the fact that the surrounding parenchyma is still quite elastic, and tends to close in upon the cavity. In chronic cases, especially in bronchiectases, the walls are so rigid that all one can hope for is drainage. But even in these cases there are more and more reports being published in which either the bronchi were cauterized or that portion of the lung excised or a portion of the chest wall resected, so as to cause the cavity to close by compression. An interesting case of the latter kind has been recently reported from Krause's clinic by Gross. The prognosis is better again in acute cases, and in younger persons, because there is less intoxication and emaciation and better recuperative powers.

In order to demonstrate the value of surgical interference in pulmonary lesions following pneumonia, I have collected the records of 93 cases following pneumonia, results of operative treatment of which are as follows:

25 cases of acute simple abscess: 24 recovered, 1 improved, no deaths.

28 cases of acute gangrene: 20 recovered, 2 improved, 6 died.

14 cases of chronic simple abscess with bronchiectasis: 6 recovered, 3 improved, 5 died.

26 cases of chronic putrid abscess, with bronchiectasis: 13 recovered, 4 improved, 9 died.

No similar effort having been made to classify the cases following pneumonia which were surgically treated, a comparison cannot be made. The reports of every case of such lesions of the lung hitherto published were carefully searched, and only those chosen in which there was a clear history of pneumonia preceding it. When the totals are computed

as to percentage of recovery, the result is quite striking, especially in the acuter cases.

	Rec'd.	Imp'd.	Died.
Acute simple abscess, 25 cases	96%	4%	
Acute gangrenous abscess, 28 cases	71.4%	7.2%	21.4%
Chronic simple abscesses, 14 cases	42.8%	21.4%	35.8%
Chronic putrid abscesses, with bronchiectases, 26 cases	50%	15.3%	34.7%

M. Recluse, in his address to the French surgical Congress, 1895, gave statistics from various sources of 117 cases of all varieties operated on between 1879 and 1895, with 68 recoveries, a mortality of 42 per cent. His own statistics between 1885 and 1895 comprise 14 cases, with 12 recoveries, a mortality of less than 15 per cent.

Schultz collected 31 acute cases due to all causes, of these 22 recovered, 73.3 per cent., and 8 died, 26.7 per cent. Of chronic cases he collected 51; of these 26 recovered, 51 per cent., 12 were improved, 23.5 per cent., and 13 died, 25.5 per cent. These were not cases following pneumonia exclusively, but from all causes. Quinke collected 47 cases.

	Rec'd.	Imp'd.	Died.
Acute simple abscesses, 7 cases,	6		1
" gangrenous abscesses, 13 cases,	7		6

We thus see that in his acute cases (simple abscesses) there were 85 per cent. recoveries and 15 per cent. deaths; in the acute gangrenous cases, there were 53 per cent. recoveries and 47 per cent. deaths.

	Rec'd.	Imp'd.	Died.
Chronic simple abscesses and bronchiectases, 8 cases,	1	5	2
Chronic putrid abscesses and bronchiectases, 19 cases,	4	7	8

This makes the percentage in his chronic cases 12 per cent. recovery for the simple cases, 60 per cent improved, and 24 per cent. died. For the chronic putrid abscesses and bronchiectases, the percentage of recovery is only 21 per cent.; percentage of improvement, 36 per cent., and 43 per cent. deaths.

In Tuffier's article he gives the following as the result of his observations:

	No. of Cases.	Cures.	Deaths
Acute simple abscesses,	18	14	4
Acute gangrenous abscesses, following pneumonia,	54	39	15
Chronic simple abscesses,	5	3	2
Chronic putrid abscesses, with bronchiectases,	4	1	3

I do not think that Tuffier's statistics of acute gangrenous abscesses following pneumonia were all due to this cause, as in looking over many of the histories I find that there is considerable doubt about the etiology, and have consequently not included such cases in my own list. The percentage of recovery thus would be, in acute simple abscesses, 77 per cent.; of deaths, 23 per cent. In the acute gangrenous abscesses the percentage of recovery would be 70.9 per cent., and of death 29.1 per cent. In the chronic simple abscesses the percentage of recovery would be 60 per cent., of deaths

40 per cent. In the chronic putrid abscesses, with bronchiectases, the percentage of recovery is 25 per cent., of deaths 75 per cent.

When these statistics are compared with those which I have collected, the marked increase in percentage of recoveries both in the acute and chronic cases is very striking, and this is entirely due to the fact that the diagnosis has during the last ten years, and especially during the past five, been made at a much earlier stage than formerly, so that the indications are now clear that, if a case of simple or gangrenous abscess of acute origin is diagnosed, and its localization determined as accurately as possible, there should be no delay in operating as soon as a reasonable time, say four weeks, has been given for a decrease in the amount of expectoration and fever. The period of time in which lung abscesses can heal spontaneously varies from three to ten weeks, and it would seem as though a judgment in regard to their spontaneous healing could be formed in four to six weeks. By operating early we will constantly improve the already favorable statistics. In the chronic cases, like the one which I am about to report, the conditions for healing are far more unfavorable than in the acute, the lung changes are more likely to remain permanent, and in addition there has been a chronic intoxication with expectoration of large quantities of pus, emaciation, and in general an unfavorable condition for the success of operation. Hence the apparently large percentage of unsatisfactory results and deaths in such cases. But when we compare statistics at the present time with those of five and even ten years ago, the improvement can already be noted. The amount of relief to these patients far outweighs the risks of the operation.

In regard to the technique of pneumotomy, the most important point to decide is whether there are adhesions present or not. The duration of the process, as Quincke has pointed out, is no criterion of the presence or absence of adhesions, and up to the present time, in spite of many rather ingenious devices and suggestions, there is no way of diagnosing their presence. It can, however, be stated, as I have ascertained from personal observation and from the statistics, that in fully 90 per cent. of all of the cases they are present. In the 25 acute simple cases which I collected, they were present in 24; in the 28 acute gangrenous cases they were present in 24, or a little over 90 per cent. for the latter, and 96 per cent. for the former. In the chronic cases adhesions were present in 11 out of 14 cases of chronic simple abscesses, or almost 80 per cent., and in two others they were produced artificially before operation, and may have been present before (Quincke). In the chronic putrid abscesses, they were present in 18 out of 26, and were produced in one artificially. In 6 they were absent. We thus see that in the majority of cases, both acute and chronic, they are present.

The Technique of Pneumotomy.—Various methods have been proposed to produce adhesions artificially, e. g., Quincke makes an incision, resects a rib, and lays zinc chlorid gauze in the intercostal space. In some cases he has even applied zinc chlorid paste, but this latter method has been quite painful. It

requires several weeks for the adhesions to form, under these circumstances, and its use has been quite limited. The two methods most employed are the suture and tampon, or a combination of both. The suture method was proposed by Roux, in 1892, and consists in suturing the parietal and visceral pleura with a round, non-cutting needle. There is but little if any danger of puncturing a superficial abscess, for in such cases there are usually adhesions. The tampon method consists in opening the pleural cavity and walling off the area which it has been proposed to drain by strips of iodoform gauze similar to its use in appendicitis, and then allowing time for adhesions to form, usually about forty-eight hours. In order to avoid opening the pleural cavity until the focus has been found, Tuffier advised an extra-pleural palpation of the lung. This has been given up as unreliable and unsatisfactory. A good way is to combine both sutures and tampon, as suggested by Krause, by sewing the strip of iodoform gauze around the edges of the wound. The pneumotomy can thus be done in one stage. A great danger, of course, in every pneumotomy is pneumothorax, with consequent collapse of the lung. When this occurs during the operation, the dyspnea may interfere to such an extent as to render an interruption necessary. If left to itself, pneumothorax usually absorbs within a few weeks. It can be avoided, or rather the lung collapse, by using one of the methods of intralaryngeal insufflation, either the Fell-O'Dwyer apparatus, or the Parham-Matas method. After the pleural cavity has been opened and the lung exposed, then it is justifiable to use the exploring needle, but not before. It can be inserted in all directions, until pus has been found, and left in place to be used as a guide. Even the use of this instrument is not without its dangers. Israel reports one case of fatal hemorrhage resulting from the puncture of a large vessel with his instrument. In regard to the incision in the chest wall, the best is the flap incision, with the convexity downwards, and as extensive a thoracotomy as possible. If we have reason to suspect bronchiectases, and especially in the case of older chronic abscesses, and when the local diagnosis is not positive, it is better to resect two to four ribs. If we have reason to suspect a contracted lung, it is better to remove the periosteum of the ribs also, so as to enable the cavity to close more readily. If the pleura is greatly thickened in the chronic cases, much time can be gained in the healing by removing it. At the present time the knife is preferred to the cautery for opening the lung itself, and then blunt dissection with the finger to explore the interior. Pus may not appear immediately, but may pour out through the drains in the course of a few days. The cavity can either be tamponed with gauze or a rubber tube used, surrounded with gauze, to prevent the pressure on blood vessels. There is danger of hemorrhage from pressure in the use of both. If there is secondary empyema present, the operation is greatly simplified. Irrigation should not be employed, as there is great danger of carrying the pus to other portions of the lung. If large bronchi communicate with the cavity, and a fistulous tract

remains, it is best to open the wound, cauterize the bronchi, and remove that portion of the lung itself (pneumectomy) which forms the wall of the abscess cavity. This has been successfully done in several cases. If the cavity shows no tendency to heal, resection of a number of ribs and compression of that side of the thorax has aided in closing the same. If the fistula remains open, patient can wear a bottle containing an antiseptic solution.

In regard to the anesthetic which should be used, chloroform is preferable to any other, and as complete an anesthesia as possible; a partial anesthesia is only justifiable when the case is in a grave condition. The patient should never be placed on the sound side, on account of the danger of pus running over from the infected side.

The following case illustrates a number of instructive features in the surgery of pulmonary lesions following pneumonia. The history is the following:

G. U., 57 years old, male, had an attack of pneumonia two years ago. Since that time he has coughed up from two to three pints daily of muco-purulent sputum, with fetid odor, so it was impossible to remain in the same room. He has lost weight and strength so that he was greatly emaciated when I first saw him. I saw him in consultation with Dr. B. F. Flannigan, of this city (Chicago); respirations were 60; the lower border of the right lung, the one which had been affected in the attack of pneumonia, was at the fifth intercostal space in the mammary line, at the sixth rib in the axillary line, and apparently perfectly movable. Anteriorly, on the right side, there was no change in percussion; behind, from the scapula downwards, there was an area of dullness about the size of the palm of the hand, and some bulging of the intercostal spaces. One could also hear a few moist rales over this area of dullness. It was decided that this was a focus of what was suspected to be a chronic putrid abscess, two ribs were resected, the eighth and ninth, just below the scapula in the posterior axillary line, the pleural cavity was opened, and the lung collapsed (upper lobe). By palpation one could feel that the lower lobe was adherent to the anterior wall of the chest, and the incision was increased anteriorly until a portion of the ninth and tenth ribs were resected in the anterior axillary line. On opening the pleural cavity, a localized small empyema was found, which opened directly into a cavity in the lower lobe, from which some fetid broken down material escaped. At the edge of the empyema a small pus cavity in the lung was opened, apparently separate from the gangrenous cavity. Patient returned from the operation in fairly good condition; pulse and respiration both remained high; he died nine hours after the operation.

The autopsy showed that there had been quite a severe hemorrhage into a gangrenous cavity in the lower lobe, which had been opened; that there was also a slight amount of free blood in the pleural cavity, which had escaped through a tear in the adhesion at the lower edge of the wound. There were firm adhesions binding the right lower lobe to the chest wall, but the remainder of this lung was non-adherent; the latter was collapsed. On section it was seen that I had opened into an area of gangrene in the lower lobe, and had opened one of a series of bronchiectatic abscesses in the lung parenchyma of middle lobe.

This case is instructive in two ways. It shows, first, that physical examinations are apt, even though carefully made, to be misleading; secondly, that, as Korte has experienced in several of his cases, lesions may be coexistent; there may be a gangrenous cavity in one lobe, and a system of bronchiectatic cavities in another adjacent one, only one of which may be opened by operation. It also illustrates what I have attempted to bring out before, that the most favorable cases for operation are the

acute ones, when the patients are in good condition for pneumotomy.

CONCLUSIONS.

1. Both acute and pulmonary abscess and gangrene following pneumonia may develop immediately, and chronic and simple putrid abscesses, with or without bronchiectases, are more remote sequelae of both croupous and influenzal pneumonia, especially the latter.

2. The most valuable points in the history are the etiology; the sudden expectoration after an apparent crisis of pure non-odorous pus in the simple abscess cases, or of fetid pus in the gangrenous variety. In the chronic cases there is usually a history of a pneumonia having preceded the condition at some considerable time previously, followed by expectoration of large quantities of pus, with exacerbations of fever, accompanied by emaciation and frequently clubbed fingers, etc.

3. Signs of cavity are seldom present. The moist rales, especially of large metallic character, are the most reliable physical signs. The character of the sputum is also of great value, whether purulent or fetid. Elastic fibers are more frequently found in gangrene than in abscess, being comparatively rare in the latter.

4. The X-ray is only of confirmatory value, as it shows chiefly thickened areas of lung, and should not be absolutely relied upon. When it shows a shadow at the same point where the physical signs are present, it is of value.

5. The prognosis of abscess and gangrene following pneumonia, medically treated, is not very favorable. Many cases of both varieties can be successfully treated in a surgical manner by pneumotomy. One of the greatest difficulties is the exact localization of the focus. The statistics which I have gathered show a marked increase in the percentage of recoveries, especially in the cases which have been reported within the last five years, over that of the preceding five or even ten years. The prognosis for the chronic cases is not so favorable. The patients are usually operated upon when in an emaciated condition, and the walls of the cavity are often rigid, so that they do not contract well after being drained, and the free communication of a bronchus with such cavities is also a great barrier. But statistics in this variety are also improving, especially when combined with excision of the affected portion of the lung.

REPORT OF SEVENTY CASES OF ACUTE LOBAR PNEUMONIA.

By J. N. HALL, M. D.,

of Denver, Col.

Professor of Medicine, Gross Medical College, Denver, Col.

Acute lobar pneumonia has, I believe, been more frequent in Colorado during the present winter than ever before. I can speak personally for the past eighteen years, and the general prevalence of the disease elsewhere confirms my position. I wish to give my conclusions derived from a study of seventy cases seen between September 1st, 1900, and April, 1901.

I will preface my paper with the statement that these must not be taken as typical of the cases of

this disease in Colorado, since many were seen in hospital and consultation work, and were naturally the severer forms of the disease.

Every case that could not be strictly classed as acute lobar pneumonia has been excluded, including many cases of broncho-pneumonia and hypostatic pneumonia.

Forty of the cases occurred in my service at the Arapahoe County Hospital, seven in that at St. Anthony's Hospital, eighteen were seen in consultation, and five were in my private practice. Of the first class, seven died within twenty-four hours, and eight more proved fatal later, twenty-five recovering. Of those in St. Anthony's Hospital, one died within twenty-four hours and six recovered. Of those seen in consultation, seven died and eleven recovered, while of the five private cases but one died, a man of seventy-one years of age.

The total deaths were twenty-four, a percentage of 34.3, far beyond the normal for the reasons above indicated.

Excluding the eight cases dying within twenty four hours, after admission to the hospital, we have a percentage of 25.8, still abnormally high because of the serious cases seen with other physicians.

Of the seventy cases, fifty-six were males, fourteen females. The disproportion is in part due to the fact that more men than women enter hospitals.

Arranged in decades, the cases were as follows:

1st decade.....	3
2nd "	16
3rd "	22
4th "	13
5th "	5
6th "	6
7th "	3
8th "	2
Total.....	70

Of the three in the first decade all recovered.

Of the sixteen in the second decade five died, a death rate of 31 per cent.

Of the thirteen in the fourth decade, six died, a percentage of 46.1.

Of the sixteen beyond forty years of age, 7 died, a percentage of 43.7.

By the sexes we have the following mortality:

Males, 22 out of 56 died, 39.3 per cent.

Females, 2 out of 14 died, 14.3 per cent.

In several cases post-mortem examination confirmed the antemortem diagnosis, in two such cases insufficiency of the mitral valve from old endocarditis being found.

Although the histories are often incomplete, previous attacks of pneumonia were noted in six of them, one man having had four attacks, one two, and four one attack each.

Distinct crisis was noted in twenty-six cases. It fell upon the fourth day in one case, fifth day in five, sixth day in four, seventh day in eight, eighth day in seven, and ninth day in one. Many cases declined by lysis, and of many more I have no record.

Three of the cases were abortive, one being preceded by a streptococcic sore throat.

The lobes involved were as follows:

Total number of lobes in the seventy cases, one hundred and sixteen.

The right lower lobe, as usual, was most frequently affected, sixteen times alone and eighteen times in various combinations with other lobes, or thirty-four times in all. Thus in practically half the cases the right lower lobe was involved.

The left lower lobe was affected ten times alone, and twenty-two times in combination, or thirty-two times in all.

The right upper lobe was the part solidified alone in eight cases, with other lobes in fifteen cases, being affected thus in twenty-three cases all told.

The left upper lobe was alone affected three times, with other lobes twelve times, or fifteen times in all.

The right middle lobe was involved alone in one case, with other lobes eleven times, or twelve times in all.

Other diseases were associated as follows:

Tuberculosis, seven times; typhoid fever, three times; erysipelas once, general sepsis once, acute rheumatism once, cerebral thrombosis once, traumatic pneumothorax once, Bright's disease (much albumen and many casts) twice, advanced emphysema once, organic mitral regurgitation (as proven by autopsy) twice.

One fatal case, noted above as having much albumen and many casts, had been exsanguinated by bleeding from the radial artery, while intoxicated.

Complications were as follows:

Empyema* five times, in two of these cases the pneumonia having practically cleared up at the time of my visit in consultation.

One case was admitted with empyema after the attack of pneumonia had subsided under the care of another physician. He had found pus with the needle, but delayed operation, and the effusion broke into the lung and caused her death within a short time after her admission into the County Hospital. Dr. Lyman, at my request, resected a rib very promptly, but it was too late. The other four cases were operated upon by resection of a rib, by Drs. Freeman, Hawkins and Fleming, and made uneventful recoveries.

In two cases serum was withdrawn from the left pleura in small amounts, the pneumonia in both cases being the predominant feature.

In thirteen cases, not including any of the seven with effusion, dry pleural friction was found, in several on both sides, and in two cases extending from the left lung to the pericardium. One of these latter cases was bled when deeply cyanotic and apparently almost moribund, nearly collapsed several days later from dilatation of the heart with loud mitral systolic murmur, but made a good recovery.

Temporary mitral leakage was noted in several other cases, and tricuspid regurgitation twice; doubtless it existed in other cases without being detected, either for lack of examination at the right time, or because of feebleness of the murmur.

*Three of these cases were seen really as sequelae of pneumonia, but are included because of their interest.

Albumen is mentioned as present in the urine in eight cases in addition to the two of Bright's disease noted, and as absent in twelve cases.

Delirium tremens occurred twice, one patient recovering. Otitis media was once noted.

Delayed resolution was found three times, the dulness remaining seven weeks, four weeks, and twenty-three days in the three cases respectively. In the last case the right chest was explored with the needle on the seventh day, because of a suspicion of fluid, but none was found. All of the cases made excellent recoveries.

The highest temperature, 106°, was in a young man who recovered.

The case with traumatic pneumothorax followed a gunshot wound of the left chest, involving the lower left lobe, with dulness, sharp bronchial respiration and high fever following. The man made a complete recovery.

Petechiae were found in a case, seen with Dr. C. P. Conroy, complicated with general sepsis, presumably in connection with septic endocarditis. The boy died on the 8th day.

One of the three cases associated with typhoid fever, seen with Dr. W. E. Shotwell, was a case of true pneumo-typhus, the right upper lobe being affected. A pseudo crisis occurred on the seventh day, followed by a continued fever, abdominal symptoms, typical Widal reaction on about the seventh day, and later by a suppurative inflammation of the hip joint, fatal soon after operation.

In one other typhoid patient, death occurred, the left lower lobe being involved about the seventh day. In a third, a man of twenty-three years, in the seventh week of the fever, after double phlebitis has occurred, the right lower, right upper and left lower lobes were successively involved. The man was desperately ill for four weeks, but made a complete recovery. Digitalis repeatedly brought his pulse from 140 or 150 per minute down to even less than 50, and I think was chiefly instrumental in saving his life.

Two of those curious cases, of which several writers have made note recently, of pneumonia simulating appendicitis, were encountered. In one the right lower lobe, in the other the whole left lung was involved. In both the abdominal pain and rigidity, with tenderness over the region of the appendix, were much more prominent during the first two or three days than the pulmonary signs. The latter patient had just recovered from smallpox when taken with pneumonia, had pericarditis by extension from the left pleura, in which friction existed, and is the one referred to above who was bled, and who had cardiac dilatation with mitral regurgitation. I think the bleeding and the infusion of digitalis saved his life.

In one case, a broken down man of 45 years, the whole left lung was affected, and erysipelas followed the attack. Subsequently he had phlebitis of the veins of the left side of the neck, with nodules in the arms and legs, regarded by Dr. F. E. Waxham, my successor at the County Hospital, as of embolic origin. A mitral systolic murmur existed. No petechiae were found, and the man to-day seems

to be recovering his health, though not ready for discharge.

A man of twenty-five years, with the whole right lung affected, and, on the seventh day, the lower lobe of the left lung, with pleural and pleuro-pericardial friction, developed phlebitis of the left leg on the ninth day, and of the right on the twenty-fifth, but recovered. At the time of the extension to the left lung, oxygen was used with great apparent benefit.

Herpes labialis, bloody sputa, dilatation or contraction of one pupil and unilateral flushing of the face were frequently seen, but the notes are too incomplete for introduction here.

Before speaking of the treatment of these cases, it seems to me proper to remark that this disease is one in which, in many instances, recovery is scarcely to be hoped for, much less expected, under any line of treatment. I speak of this because in pneumonia, as in other diseases, new methods of treatment are constantly being brought forward and as constantly discarded by a certain class of therapeutic enthusiasts. As usual, such men claim 100% of recoveries. The outcome is always the same, and is identical with a certain much vaunted treatment for typhoid fever, of which we have read so much for several years. When tested in a separate ward of a Government Hospital by its originator, not only did some of his cases die, but more died than the average for the whole institution, with a dozen other physicians in attendance. Fortunately, after such an outcome, we are spared a repetition of the mode of treatment in the journals.

Pneumonia should be recognized as a common cause of the fatal termination in several classes of patients. Those advanced in years should be placed first in the series. Those suffering from tuberculosis, from serious heart disease or kidney disease, from chronic affections of the digestive tract, from extensive emphysema, from alcoholism, and from exhaustion by recent acute disease, follow. It is not reasonable to expect recovery in a large proportion of such cases, and he who claims such a result must certainly demonstrate his claim in an unequivocal manner, or be distrusted, to use no stronger language, by those of extensive clinical experience. In large series of cases a mortality of less than 20% is exceptional unless the statistics deal with special classes, as, for instance, the young healthy men constituting an army.

The increasing number of deaths from pneumonia in years past does not necessarily signify that the disease is becoming more malignant. The disease is particularly one of advancing years. The decreasing mortality from tuberculosis, diphtheria, typhoid fever and other infectious diseases leaves more individuals to grow older and thus die of the diseases peculiar to more advanced ages. It is entirely probable that the mortality from pneumonia will continue to increase, for the disease will continue to be the final infection in those escaping death from other causes, and will increase in importance with their decrease. This factor is overlooked by too many writers.

Treatment.—The immense relief to the right heart and the pulmonic congestion by judicious venesection

is so striking in certain instances that I feel that it should oftener be employed. Of the two patients bled, one, a feeble old woman, died, although temporarily relieved. One recovered who certainly had every appearance of dying within a few hours, and a third patient, not included in this series, in the service of Dr. H. B. Whitney, whom I saw bled, recovered from an even more desperate condition. My experience leads me to bleed more frequently, from ten to twenty ounces, in selected cases, when the circulation is seriously embarrassed, for the occasional successful result justifies many attempts.

As regards local applications, sinapisms and turpentine stupes were often used during the early painful stages, and generally a cotton jacket with camphorated oil later. I certainly do not expect to return to the use of the jacket poultice. Ice bags were frequently applied to the chest and at times to the head in great pyrexia, with benefit. Occasionally cold bathing was used, but no medicinal antipyretics.

Sleeplessness demands an opiate rather than the more depressing hypnotics. Dover's powder and hot whiskey in combination were frequently found very effective for this symptom, as well as for painful cough.

I believe many physicians withhold opiates too much in the beginning painful stages. The fall in respirations from 50 to 60 per minute to 30 from a hypodermic injection of morphine in one suffering from the painful complicating pleurisy so often seen this winter is wonderfully striking, and equally reassuring to the patient. The abdominal symptoms spoken of may entirely disappear under this treatment. The quieting effect upon the heart, especially in beginning pericarditis, is equally advantageous.

I believe the free use of strychnia in recent years is a distinct gain. Most of these patients who suffered from cardiac distress received one-thirtieth grain every four, three, or even two hours, subcutaneously if the circulation was not good.

Aconite and veratrum were used in a very few cases with bounding, hard pulse and flushed face, and probably with some benefit. More commonly liquor ammoniac acetatis or the sweet spirits of nitre was used, and I think with equally good result. I have no doubt that very early free venesection is better than any of these remedies in selected cases, but very few if any of these were suitable ones.

In cases with increasing heart weakness, digitalis, generally the infusion, was used freely. During the height of the febrile period, doses of half an ounce every two hours frequently failed to lower the pulse-rate, but, with the fall of temperature, the slowing was notable; I have already stated that, in several instances, the recovery seemed to me more due to this drug than to any other.

Alcohol, generally as whiskey, has been frequently used where demanded, often in combination with strychnia and digitalis, and often with apparent benefit.

I think the use of oxygen, which we have employed frequently, tided over one of the patients already mentioned in this list, and also one seen a

year ago. In the vast majority of patients I think it is nearly useless. I have certainly seen it used in some private houses where the effort might well have been spent in obtaining better nursing and in hydrotherapy.

In a few of these cases and in others which I had the privilege of watching, in the practice of my colleague, Dr. G. E. Tyler, at the Arapahoe County Hospital, antipneumococcic serum was freely used. Dr. Tyler has published his conclusions in a recent number of the *Journal of the American Medical Association*, with my own views, brought out in the discussion of his excellent paper. I feel like emphasizing more strongly at this time the ideas there set forth. Until we deal with a disease more uniform in its bacteriology, we cannot expect any results from serum therapy comparable to those in the treatment of diphtheria.

A study of these cases, with casual observation of many others seen during the Winter in the practice of my hospital colleagues, leads me to believe that the pneumonia of this season has been less typical than during any period of my practice. It has been accompanied with more of the pain-producing pleural element than usual, with frequent palpable friction, in two cases extending to the pericardium. Para-pneumonic empyema has been more frequent than I have seen it heretofore. This statement is not based altogether upon the seventy cases reported in this series, since some of these were, in a sense, selected cases, but, in part upon the statement to me by several surgeons of this city that more operations for this disease have been made here of late than ever before, and generally in cases following pneumonia.

The course of the disease has been very irregular in many instances, and termination by crisis less frequent than usual. I regret that owing to the fact that about one-third of the cases were seen but once, no exact statement can be made as to the frequency of this termination.

The high mortality, 34.3%, is, of course, far beyond the just percentage for all cases, since many moribund cases are sent to the hospitals, and the cases seen in consultation are the especially severe ones. The mortality of the disease is better shown by the vital statistics of the whole country, showing that many more cases than usual proved fatal.

The high mortality of pneumonia in certain winters since 1889-90 has been attributed rightly to the epidemic presence of influenza. During the present winter another factor has been present, although I cannot offer any direct bacteriologic evidence as to its influence. I refer to the abnormal frequency of streptococcic sore throat, and of streptococcic pyemia. Thus in one case mentioned, a physician recovering from the former trouble was sent on a vacation, to recuperate, but returned on the fifth day with an abortive lobar pneumonia. Two patients having entered with other diseases, were stricken in the same ward on the same afternoon, at the time of the great prevalence of the sore throat mentioned. In view, however, of the lamentable

lack of evidence as to the bacteriology of the pneumonic inflammation, I shall not pursue this part of the subject further. In extenuation I may say that the physician who did what was absolutely necessary for his patients during the winter months past had little time or strength for unessential details, however interesting.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended November 1, 1901.

The Surgery of the Ureters.—The omission of two words and a date from a recent editorial comment in this journal on "Ureteral Implantation," transformed a harmless criticism into an inaccuracy that would have been absurd were it not unjust to the eminent men identified with this line of pelvic surgery. Since the older days, but a quarter of a century ago, when injury to a ureter meant extirpation of the associated kidney, the surgical treatment of disease or injury of the ureter has been revolutionized. The conservative tendency which has pervaded the entire field of surgery is nowhere better exemplified than here. No longer, save in extreme cases, is Simon's method of nephrectomy the only resource when the ureter has, in the course of a hysterectomy, been torn or severed by the knife. There have been numerous devices suggested and put into actual practice to remedy this grave accident without sacrifice of a healthy functioning kidney. Implantation of the injured ureter into the bladder, rectum, vagina, and elsewhere has been attempted, not always with success in the individual cases, but ever with an onward movement toward ultimate success in the development of the method. The operators identified with this brilliant advance in abdominal and pelvic surgery are many. Time and space would forbid here a complete record of the names even of the men in this country alone who by experimental research on dogs and other animals, or who by actual performance on the human being, have saved valuable lives without loss of organs that would otherwise have been invariably sacrificed. Van Hook, Kelly, Baldy, Boldt, Bovee, Emmet, Baldwin, Penrose, Fullerton, Krug, Noble, and many others—all eminent authorities in their chosen field of work—are included among these bold and successful pioneers in ureteral surgery; and Laphorn Smith, of Montreal, has just contributed a paper on this subject to this journal. While it will not be convenient nor advisable to give here a complete historical review of the development of this line of surgical intervention, mention should be made of the various methods that have been resorted to in the effort to save an injured ureter. These may be grouped under two great

headings, namely, those involving a reunion of the severed segments of the ureter—uretero-ureterostomy in its four main forms of transverse end-to-end, oblique end-to-end, the end-in-end, and the lateral implantation or end-in-side—and the various methods of implantation of the proximal extremity of the ureter into other viscera, mainly the bladder—ureterocystostomy. The operations performed by these divers methods now number very many, and the results have in the main been most gratifying. The anastomosis of the ureter is decidedly the most difficult in its technique, but if there has not been much loss of tissue, this is the proper treatment to pursue. The oblique end-to-end method probably gives the best results, with less danger of ultimate ureteral stenosis. Implantation into the bladder is a much easier operation than ureteral anastomosis, hence its popularity among abdominal surgeons. It should also be noted, however, that in many of the operations the primary injury to the ureter had resulted in a uretero-vaginal fistula which could more readily be remedied by this method of operating. These secondary implantations have far outnumbered those performed intraperitoneally at the time of the original injury to the ureter. Vesical implantation is indicated when there has been much loss of ureteral tissue, in the presence of ureteral fistulæ, or when the ureter is so disorganized that the methods of anastomosis cannot be applied. It is preferably performed by the abdominal route. Implantation into the rectum or colon is apt sooner or later to be followed by infection of the ureter and kidney with subsequent death of the patient; it should be employed only when other methods are impracticable, as in ectopia vesicæ, or in grave injury or involvement of the ureter and surrounding parts from cancerous and other changes. Implantation of the ureter into the vagina or onto the skin surface of the abdomen are both open to disadvantages that are obvious, such as the necessitating the wearing of cups and other apparatuses. Bovee states that skin-grafting of the ureter has been done but ten times, and vaginal implantation but three times.

It will be seen therefore, from this condensed

summary of ureteral surgery that a new field of considerable dimension has been opened in surgical technique. Already the surgery of the ureter has won for itself an established place, and its literature commands the respectful attention of the general as well as the pelvic surgeon. Its annals are full of magnificent successes and all honor is due those who by their untiring efforts have developed a new means of aiding afflicted humanity.

Tetanus From Antitoxine Serum.—The recent calamity in St. Louis, by which a large number of children lost their lives from lockjaw following the injection of diphtheria antitoxine, is capable of but one interpretation. The serum was contaminated with either the bacilli or the toxine of tetanus. Just how this happened, and who is responsible, are questions upon which we do not venture an opinion. The reports thus far obtained are from the newspapers, and the official investigations must be completed before blame can be attached to any one; but the bare facts speak for themselves.

The facts appear to be these. The horse from which the serum was taken was inoculated on August 10th with the diphtheria poison and the antitoxine was withdrawn from the animal on August 24th. It is this serum that is accused of causing the trouble. But this same horse was inoculated again with diphtheria on September 22d, and several days later he developed tetanus, and was shot on October 3d. After this second inoculation, and at the time when he must have had in him the germs of tetanus, he was bled in order that another supply of diphtheria antitoxine might be obtained. But this latest supply of serum, it is claimed, was not used. Hence the inference is that the horse must have contained the poison of lockjaw before August 24th, although he did not exhibit the disease until more than a month later. This seems highly improbable.

We believe that this is not the first time that tetanus has followed the administration of antitoxine serum. An instance is reported in Italy in which a group of patients thus treated all developed tetanus. But whenever and wherever it happens, it always points to a faulty or careless technique. The poison (germ or toxine) of diphtheria does not cause tetanus, unless it is contaminated with the specific germ or toxine of tetanus. In other words, the two diseases are distinct, and it is the business of the manufacturing bacteriologist to keep them separate.

Next to the immediate sacrifice of life the worst thing about this St. Louis disaster is the loss of popular confidence which it will involve. The peo-

ple, even the most intelligent of them, will not readily overcome the horror of antitoxine serum which this holocaust will inspire in them. The physician himself will not like to feel that he is running a risk of giving lockjaw to a patient when he uses the antitoxine of diphtheria. It will be a new and very disagreeable idea to many physicians that such a thing is possible.

Of course, reason tells us that this was a mere accident, and that it should not count for too much in the face of the tens of thousands of injections that have been given harmlessly, and of the good that has resulted. While this is true, the members of the medical profession will look for a satisfactory explanation of this calamity. St. Louis owes it to herself and to the world to make the investigation thorough and complete.

The Army Canteen Again.—Lieutenant-General Miles, Commander-in-Chief of the U. S. Army, has recently declared himself in favor of the law abolishing the canteen. He has thus reversed his former opinion on this subject, and is hailed by the prohibition people as an important convert to their cause. His principal argument in favor of maintaining the present law is that the abolition of the canteen has not prevented enlistments in the army or increased the number of desertions. With all due respect for General Miles we cannot help thinking that this argument is a very inadequate and unconvincing one in such a matter as the canteen. No one would seriously suppose that the question was to be decided by the number of enlistments and desertions in the army. Such an argument for such a subject is indeed far-fetched.

We have believed from the beginning that the abolition of the canteen was an unwise measure, and we have not hesitated to say so. For some time past, however, we have thought the country at large would do better to await further reports from the War Department before again consenting to the agitation of this question. Figures and statistics sometimes tell a plainer tale than over-heated rhetoric. Fortunately the forthcoming report of the Surgeon-General contains some eloquent figures on the subject.

The admission-rate for alcoholism in the army for the year 1900 was 15.34 per thousand of strength, as compared with 14.49 in 1899, and with 28.67, the mean rate for the decade, 1889-98. Troops serving in the United States in 1900 had a rate of 22.42. "The steady decrease of late years in the admissions for alcoholism among the men of the Regular Army is a matter of congratulation." This decrease, it is to be observed, was during the period before the

abolition of the canteen; and, according to the report, military officers are almost unanimous in their opinion that this was mainly the result of the establishment of the canteen. The following are the figures in detail: Mean annual rate for the decade 1879-88 per thousand of strength, 56.68. For 1889, 41.41; for 1890, 40.73; for 1891, 40.01; for 1892, 37.23; for 1893, 33.97; for 1894, 30.94; for 1895, 30.11; for 1896, 29.06; for 1897, 27.86. The record was here interrupted by the Spanish-American War; but so far as it goes it is significant of a steady improvement in the habits of the American soldier.

Let us now await the returns since the abolition of the canteen.

The Physical Stigmata of the Criminal.—Dr. W. Norwood East, the deputy medical officer in the Convict Prison, at Portland, England, believes, evidently, that the criminal carries with him some physical signs of his degeneracy. In the *Journal of Mental Science*, for October, he contributes a carefully written paper on "Physical and Moral Insensibility in the Criminal." Dr. East, like every sensible man, knows that there are criminals and criminals. In other words, the various criminal classes must be distinguished and differentiated. The accidental criminal is one kind; the occasional criminal is another; and the professional criminal is still another. These facts are, of course, patent to scientists, but the average declaimer against "sin" and "materialism" fails to distinguish them. A case in point is that of the assassin, Czolgosz, who was an "occasional" criminal and in no sense a "professional" one. He offended on one particular occasion only and then in obedience to a vicious dogma which had been preached into him. He was in every sense sane and responsible, and has been pronounced so by every alienist who has studied him or his history. In such a criminal the stigmata of degeneracy would not necessarily be found, and, even if they were found, would not necessarily indicate his irresponsibility.

Dr. East found in 100 convicts at Portland Prison that the three classes, (1) accidental, (2) occasional, and (3) professional criminals, represent three degrees of moral and physical sensibility, and that the difference in these respects is on the whole greater between the first and second than between the second and third for moral sensibility, and the reverse for physical sensibility. Dr. East's general conclusion is that sensibility is impaired in the criminal, and most so in the professional criminal; and this is quite in accord with the inexpert observation of most persons. In the brain of the professional criminal the number of conscious sensory

elements is reduced, and hence the range of ideation is less. The paper has value as a contribution to both the physiology and psychology of crime.

The Wrath of the Antivivisectionists.—A journal published in Philadelphia in the interests of a local antivivisection society, has assailed us in choice language for not having yet published a letter which was addressed to us recently by the President of the American Humane Association. The letter referred to was written ostensibly in reply to an editorial comment in the *Philadelphia Medical Journal*, but in effect it was merely a continuation of the method of controversy which Mr. James M. Brown adopted in his disastrous encounter with Dr. Keen. The pith of the letter is in a series of quotations from medical literature—but the accuracy of the antivivisectionists in their statement of alleged facts and in their use of quotations has been so seriously discredited by Dr. Keen's criticisms (published in former numbers of this journal) that we are unwilling to enter into a controversy on such unreliable grounds.

If, however, it is any satisfaction to the antivivisectionists, we are quite willing to acknowledge that there have been some reckless men and some mistaken men in the medical profession; that there have been some men who have committed errors, and others who have performed useless operations, and others, again, who have mistreated cases, and still others who have performed improper experiments. There have even been physicians who have been guilty of crime. We do not claim that the whole profession is immaculate. But all this is no reason for the indiscriminating opposition to scientific medicine which a few clamorous extremists are forever setting up.

If Dr. Keen, on his return, wishes to resume this subject (for which we candidly think there is no necessity), we shall, of course, open our columns to him and to his opponents. In the meantime the antivivisectionists may find what comfort they can in calling us hard names.

Municipal Control of Smallpox.—While it is of great importance, when smallpox actually exists in a community, to care for the disinfection of all persons and things that come in contact with the patient, the real control of smallpox depends upon the thoroughness with which vaccination and revaccination are carried out in that community. There is great danger that we shall forget this essential prophylactic feature and that the statistics of vaccination and of revaccination in relation to smallpox in the German army shall have become so familiar that they shall be treated with contempt. In 1890, the

year in which the eleventh census was taken, there were but 398 deaths from smallpox in the United States, and the number of deaths since that has been small. During the present year, however, owing to the fact that the immunity conferred by vaccination is gradually being exhausted, several municipalities have seen the beginnings of smallpox epidemics. The one way for these communities to control this pest is by insisting that every individual who has not been successfully vaccinated within the past 5 years shall submit himself to vaccination at once.

Cataract Extraction in Extremely Advanced Age.

—At one time the operation of "reclination" of the cataractous lens in advanced age, was frequently performed, but it has been almost entirely supplanted by the operation of "extraction." Mendel, the second assistant at Hirschberg's clinic, observed that among the 34 patients who were over 80 years of age among the 1645 operated on for nuclear cataract by means of extraction, unfavorable results were obtained in but one case. Notwithstanding these valuable statistics, it must not be lost sight of, that in individuals over 80 years of age, a corneal section constitutes not only an exquisitely delicate procedure, but one coupled with many difficulties, such as atrophic thinning of the tissues, arteriosclerosis, and constitutional involvements, embracing the lungs, heart, genito-urinary system, and even the brain. Complications, such as prolapse of the iris, loss of vitreous, and infection, are necessarily more liable to occur, and in one of Mendel's cases pulmonary edema in consequence of an existing heart lesion followed a cataract extraction. With scrupulous care, however, extreme old age does not materially influence the prognosis of cataract extraction.

The *Lancet* announces in an authoritative way that the rumors about the ill health of King Edward are unfounded; that the King has had no surgical operation performed, and that his health is not seriously impaired. These rumors have been persistent and have seemed to have something authentic in them. Perhaps it would be better if our English friends adopted the American custom of taking the public fully into the court confidence in the matter of the health of the ruler of the State. Let us hope sincerely that the English people are to be spared the horrors that have been threatened in these reports.

Most persons will concede that the barrel (with a woman inside of it) which recently went over Niagara Falls, displayed great powers of endurance. But why the woman herself should claim any great

merit for the feat, is not evident. She risked her life, as many suicides have done at Niagara, and was no more brave than they. In fact, she was not so brave, for she had a barrel and they had none. From the standpoint of physical endurance the venture proves nothing of practical value, for it is supposable that anybody else in like circumstances, and in a like barrel, would have pulled through. The next barrel that tries it may strike an extra hard rock and go to pieces—and then there will be one barrel and one fool the less in this country or in Canada.

Current Comment.

THE ELEVATOR DISEASE.

It looks as though people with weak hearts had, after all, better climb ten flights of stairs than effect the ascent by means of the lift. This convenient institution is becoming ubiquitous. We soar up to the topmost story of the sky-scraping flat, we descend through geological strata to the twopenny tube by its assistance. We thought we were thereby saving our vital energies and lengthening our lives. The doctors seem to hold another opinion. Lift attendants have died sudden deaths; people with weak hearts have noticed ominous sensations when in the elevator. We are told the sudden transition from the heavier air at the foot to the lighter air at the top is extremely trying to the constitution. Even millionaires and bishops and aldermen are now voluntarily tramping up stairs and avoiding the swifter but insidious route. In fact, a new disease has swung into our ken, 'lift-men's heart.' We have all of us been risking this malady without knowing it. It is true most people have experienced the singular sensation of internal collapse when the lift floor sinks beneath the feet, but none of us suspected the result might be so serious. Every new notion for health and comfort seems to bring its particular Nemesis.—*The London News*.

THE "COWARDLY" ALIENISTS.

Since the murder of President McKinley we have been watching carefully for the editorial and expert opinions of certain alienists and neurologists concerning the responsibility of the sane criminal. When the public conscience is not aroused it is very easy to be as bold as a lion with dogmatic denials of freewill, and with dogmatic assertions that structure (of the brain, for instance) absolutely rules function. If this is so the criminal is impelled to do his deeds by his neurologic and cerebral mechanism, and the conclusion is inevitable that he is irresponsible and that the asylum should be his reward, not the death sentence. Punishment must be out of the question when the criminal is irresponsible, and there can be no responsibility when there is only fatalism and materialism. Strangely enough the materialistic alienists and the determinists have not said a word about this highly important fact since Czolgosz committed his crime. They should have the courage of their philosophy. We are glad, however, that they are wisely, if cowardly, silent. *Vox populi* is, in this case, truly *vox Dei*, and righteous public sentiment, outraged by a science so ultra that it becomes unscience, might too easily visit on the whole profession the punishment of the sins of a very few hobby riders.—*American Medicine*.

SCIENCE AND POETRY.

Rather foolish discussions are sometimes raised as to which has been of the most benefit to the world—poetry or science. One man has gone so far as to declare that if the question were put to England, "Who is your greatest man? Whom would you choose if forced to decide between the shining names in science, art, statesmanship, or invention?" the answer would be "Shakespeare," that

his would be the one influence, the one great light England would not lose for all her other acquisitions and achievements put together. With the Darwin letters and scientific victories fresh in our minds there would be hesitancy in subscribing to this sweeping assertion.

Coleridge said that the antithesis to poetry is science. Darwin sustains the statement when, in his autobiography, he tells us that when young he was fond of reading books and used to sit for hours reading the historical plays of Shakespeare, and the poems of Byron and Scott. "Later in life," he says, "I wholly lost, to my great regret, all pleasure from poetry of any kind, including Shakespeare."

This is a heavy price to pay even to be the discoverer of the principle of natural selection.

—*The Indiana Medical Journal.*

THE DOCTOR'S BILL.

The physician himself is at fault for the remissness of his patrons in paying their dues. Indeed, our profession has been brought under contempt through the adage—"As hard to collect as a doctor's bill." Tradesmen are promptly paid the entire amount of their bills. The doctor would be, too, if he would only put up a little fight for it; but, without a particle of business insistence, with childlike timidity, he humbly submits, without pretest, to being paid at any odd time, in a haphazard way, at long intervals, and then, usually, only a part of his bill, instead of the whole of it. Eventually, payments become more and more remote, while the amounts at each payment dwindle in proportion.—*Dr. G. R. Patton, in The Northwestern Lancet.*

Reviews.

The Circulation in the Nervous System. By Herman Gasser, M. D. Journal Publishing Company, Wisconsin. 1901. \$1.00.

Dr. Gasser has devised what he believes is a new theory regarding the nervous system. Briefly stated this theory is that there is a continual circulation of energy from the central nervous system to the periphery and back again, and he believes that this is the only satisfactory method of explaining the various phenomena of sensation, motion and mind. The importance of the theory, according to him, is that it is incompatible with the neuron theory, that is to say, if the nervous system is composed of isolated units, such a circulation could not occur. As a matter of fact, Dr. Gasser merely re-states, in a very confused and unsatisfactory form, a fact that has been known to physiologists almost from the beginning of the study of physiology: that certain influences emanate continually from the ganglion cells in the brain and spinal cord, and keep in activity certain tissues in the human body. He misunderstands the neuron theory to this extent, that in that theory there is no suggestion whatever that impulses are not transferred from one neuron to another. As a matter of fact, if he would take the pains to study the phenomenon of motor innervation from the cell in the cortex to the cell in the muscle, he would find that at least two neurons were concerned in the chain, and that therefore, according to the neuron theory, one complete break must have occurred. And yet everyone is agreed that it is the impulse from the motor cell that determines the contraction of the muscle. The only point that the up-holders of the neuron theory insist must be admitted is that hitherto no satisfactory demonstration of a physical connection between neurons has been given. And we are therefore forced to suppose that physical connection exists which we cannot detect by our present methods of research, or that the dendrites are capable of moving and therefore of coming in contact with the neurons or fibres at the termination of the axis cylinder; or that the transference of energy takes place by a form of induction. We regret that we cannot share the author's opinion regarding the importance of his theory, but congratulate him upon the industry with which he has attempted to adapt it to the phenomenon of nervous activity. Of course, as he states at the end of his book, no theory will alone solve the

problem, and we fear that his effort at systematization of our "raw facts" will not add very greatly to our knowledge. [J. S.]

Merck's 1901 Manual of the Materia Medica. Compiled from the most recent authoritative sources and published by Merck & Co., New York and Chicago. 282 pages. \$1.00.

This little manual, so far as its general appearance and comprehensive collection of prescriptions are concerned, has maintained its previous excellence. There is a valuable compilation of the various medicaments, which are classified according to their physiological actions. In addition the manual contains a list of antidotes, modes, of administration, dosage and synonyms. We feel obliged to state that the synonyms are sadly deficient. Lobar pneumonia is classified as a synonym of pneumonitis, while modern medicine has definitely established lobar pneumonia or croupous pneumonia as a general infection with constant pulmonary lesions, but not an inflammation confined to the lungs. Under the term "meningitis," cerebrospinal fever is given as a synonym; it needs but little comment to point out the well authenticated fact that while cerebrospinal fever is anatomically characterized by an inflammation of the cerebrospinal meninges, meningitis is not necessarily cerebrospinal fever as stated in the manual. The term "dandruff" may be correctly applied as an associated condition in pityriasis capitis, but not to all forms of pityriasis, as would be inferred from the definition of the manual. The term "acute articular rheumatism" is to be approved instead of the general term "rheumatism" as hitherto employed, although the obvious infectious character of the disease has justly given the term "acute rheumatic fever" the preference.

In the treatment of ivy poisoning a highly recommended drug, "grindelia robusta" has been omitted. Calomel has not been classified under the "diuretics." We would suggest that as a definition of "cancrum oris" the term "gangrenous stomatitis" would be preferable to "foul ulcers inside the lip and cheek." Hematuria is not necessarily renal hemorrhage as is found in the manual, because blood in the urine may come from the ureters, bladder or urethra. With the exception of some of these ambiguous, and in some cases erroneous definitions, the little manual forms a valuable ready reference book for the physician.

[M. R. D.]

Hand-Book on Sanitation. A manual of Practical and Theoretical Sanitation. By George M. Price, M. D. Small 8vo., 306 pages and index. John Wiley & Sons. New York.

This is a condensed sketch of the methods and principles of modern sanitation, but is nevertheless ambitious in purpose, as the following sub-title shows, "For students and physicians, for health, sanitary, tenement-house, plumbing, factory, food and other inspectors, as well as for candidates for all sanitary positions."

It is obvious, that in a little over three hundred small pages, only brief consideration can be given to each topic. There is, however, much information in the book. By adopting a concise style and avoiding argument and discussion of irrelevant matter, a large amount of knowledge is packed in a small space. The author's experience has been principally in New York city, which leads him to discuss at some length the tenement-house problem, so striking a feature of life in that city. The last phase of legislative regulation of the construction and supervision of tenement houses is declared to be a satisfactory one. It will go into operation in January 1902. The law as given in the book, presumably in full, occupies thirty-two closely printed pages. It provides for over two hundred officials, most of which are inspectors. This seems an enormous number, but we are told that New York contains over 45,000 tenement-houses.

Many data of practical value are given. It is to be regretted that the tables for making various engineering calculations are rendered misleading by the use, without notice, of the English gallon, instead of the U. S. gallon.

This error is due mainly to relying upon an English publication.

The work is well printed; it is only sparingly illustrated. [H. L.]

Report of the Outbreak of the Plague at Sidney, 1900.
By the Chief Medical Officer of the Government and President of Board of Health.

The most important part of this very creditable publication is the report of the General Medical Officer of the Government, and President of the Board of Health to the Premier of the Colony. In this are given the statistics of the plague, an inquiry as to its causation, and a full account of the measures taken to combat it. As this report has already been treated editorially in this journal, we shall refrain from any careful analysis of its contents, contenting ourselves with the statement that it is one of the most thorough and scientific reports of a plague epidemic, that it has ever been our pleasure to read; and that the measures employed in combating this epidemic were eminently characterized by their sanity and effectiveness. Following this report there are a number of appendices in which the more scientific aspects of the subject are considered. Thus, Tidswell describes the bacteriology, starting with a complete account of the plague bacillus, the frequency of its occurrence in rats, which was 23 out of 115 cases examined, and a careful discussion of the significance of skin lesions as points of inoculation. Salter discusses the clinical aspects, and tabulates the symptoms in convenient form for reference. McLeod writes upon the eye lesions, and Taylor, Jamieson and Sanders give the notes of the autopsies upon 24 cases. The appendices following these belong to the department of hygiene and therapy. Thus Salter gives the result of all cases treated with the Yersin-Roux serum. There are other appendices upon the regulations employed for the Haffkine inoculations and the effect of disinfection of different areas of the town, and various notices and reports which were issued during the epidemic. The report is excellently illustrated by charts, maps, and a few pictures of plague bacilli and infected rats. [J. S.]

A Text-Book of Embryology. By John C. Helder, M. D., Professor of Anatomy in the Medico-Chirurgical College, Philadelphia. Second Edition, thoroughly revised. Octavo, 405 pages; illustrated. Philadelphia and London. W. B. Saunders & Co., 1901. Cloth, \$2.50.

Embryology is at present the recognized starting point in the study of human anatomy. The student who has a good general knowledge of the development of the organism is prepared to appreciate the significance of many adult structures that would otherwise be entirely beyond comprehension. In order to give the student of medicine the necessary embryological data, the teacher is obliged to modify the literature on the subject to a great degree in order to bring it within the grasp of a class of men whose aim it is to become practical physicians rather than pure scientists.

Dr. Helder's book, which has now reached a second edition, is designed to set forth the principal features of human embryology. The essential features of the embryology of the lower forms are utilized in order to fill in the gaps left in the knowledge of the human type by absence of direct observation. Advantage has been taken of the recent work of Peter's on "The Embedding of the Ovum" to rewrite the chapter on the decidua and the placenta. Changes have also been made in the chapter treating of the chorion.

The book is admirably adapted to the needs of the medical student, who will find in its pages just the amount of information that he needs for an understanding of the essential features of the subject. [J. M. S.]

Personal Experience with Uterine Fibromyomata.*
HENRY D. INGRAHAM, M. D., of Buffalo, N. Y. In the full paper mention is made of a large number of cases of uterine fibroids which I have treated by various methods during the past sixteen years. Also my earlier

experience with the use of drugs, especially ergot and hydrastis. Later, my experience with electricity, the thyroid extract, the dessicated mammary gland, and stypticin. Although I have used ergot freely in many cases, it is only in a very few that it has had any effect upon the hemorrhage, and possibly hydrastis has in some cases. Stypticin has in my experience appeared to check the excessive flow better than any other drug. I have never derived any special benefit from the use of the thyroid extract or dessicated mammary gland, and consider their use dangerous, by their effect upon the general health. I have used electricity quite faithfully, visited Apostoli, and saw him use it, and continued its use some time after my return. In a very few cases it stopped the growth of the tumor, checked the hemorrhage in some others, but I do not use it now as the results are not satisfactory. I think it dangerous in cystic or rapidly growing tumors, although I never had any bad results in its use, because I have always been very careful, and used it only in selected cases. Doubtful if it does any good, excepting in checking hemorrhage in some cases.

I have had seven cases of quite large fibroids complicated with pregnancy. In five miscarriages occurred spontaneously. In one it was induced, and in the other the growth almost completely filled the pelvic cavity, and the four and one-half months fetus being above it, a hysterectomy was necessary. Patient made a good recovery.

One case mentioned is that of an unmarried woman who was past 64 years before the fibroid began to show signs of its existence. For some time it was dense and hard and grew slowly, but for the past few months it had become cystic and increased in size rapidly. This patient has had severe cerebral symptoms upon three different occasions, which I believe due to some particles of the disintegrating tumor becoming detached and carried to the brain, producing these symptoms. Upon one occasion she lost sense of motion and sensibility of the right side for over two weeks, and did not know the members of her own family for the same length of time. During the height of this attack the temperature was 101 F., and pulse 96.

About a year later she had a similar attack, and a few weeks ago another one, but milder, and no rise of pulse or temperature.

I believe that fibromyxomata, although considered benign in contrast to malignant growths, such as carcinoma, are by no means harmless, but expose the patient to great and increasing risk, frequently risk of life, partly due to their own inherent conditions and partly to the complications which may arise. All cases of fibroids should be carefully watched. If they are not giving any trouble or increase in size, let them alone, but continue to keep the patient under observation. If they do occasion trouble to any extent, which is gradually getting worse, or if the growth is gradually increasing in size, then the proper thing to do is to remove it before dangerous complications occur. If there be adhesions or necrosis of the tumor or pyosalpinx, then the danger of the operation is greatly increased.

If cardiac disease or hydronephrosis result as a complication, the removal of the tumor does not relieve these conditions. Waiting for the menopause to relieve the diseased condition is often like holding out false hopes to the patient, as the trouble may become worse than then before, or it may all develop after that period, as shown by the last case mentioned.

If any treatment is necessary, and the patient is in suitable condition, then a radical operation should be done. There is no excuse whatever for palliative or temporizing treatment at the present day.

Sychois.—In *L'Independance Medicale*, (June 26, 1901) Balzer discusses sychois, a skin disease consisting of nodules and pustules, with crusts and ulceration. The skin may be deeply infiltrated. It is not as a rule painful. It lasts from two to four years or longer. It occurs only in the bearded part of the face, and causes alopecia. It may be parasitic, and is generally associated with long standing coryza. In the treatment, this coryza must first be cured by the use of tannin and sulphur locally. For the sychois a saive of oil of tar, or ichthyol is useful. Sulphur, zinc, calomel, and mercury may prove beneficial. In very rebellious cases corrosive sublimate solution will do good, 1 to 1000 to 1 to 5000, applied at night. Iron, arsenic, and calcium phosphate are given internally. [M. O.]

* Original abstract of paper read before the American Association of Obstetricians and Gynecologists, Cleveland, September, 1901.

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

University of Pennsylvania.—Dr. Charles K. Mills has been elected clinical professor of nervous diseases in the University of Pennsylvania, having resigned his position as professor of mental diseases and of medical jurisprudence; Dr. William G. Spiller has been elected assistant clinical professor of nervous diseases, and Dr. Charles W. Burr professor of mental diseases.

Society Meetings Next Week.—The following sections of the College of Physicians will hold meetings next week: Tuesday evening, November 19, Section on Ophthalmology; Wednesday evening, November 20, Section on Otology; and Thursday evening, November 21, Section on Gynecology.

Philadelphia Hospital.—Bids have been received for the new buildings soon to be erected in the Philadelphia Hospital, the children's pavilion, maternity pavilion, and pavilion for contagious skin diseases. These are to cost altogether \$80,000. The Councils Committee on Charities were asked to appropriate, in 1902, \$80,000 for a pavilion for consumptives, \$10,000 for a new clinical amphitheatre, \$85,000 for a new obstetrical and gynecological pavilion, and \$50,000 each for a new pavilion for nervous diseases and general medicine. Dr. John V. Shoemaker, president of the Board of Charities, recommends these improvements. It is also rumored that the almshouse and hospital for the insane are to be moved to Petty's Island.

Tetanus After Vaccination.—In Philadelphia and Camden several cases of tetanus occurring in children after vaccination have been reported. One case is doing well upon the antitoxin treatment, while six have died. A few cases have been brought into the city for treatment from the country.

Mütter Lecture.—The Committee on the Mütter Museum of the College of Physicians of Philadelphia announce that the Mütter lecture for the year 1901 will be delivered Tuesday, December 3 at 8 P. M., in the Hall of the College of Physicians. Dr. Harvey Cushing, of Baltimore, will deliver the lecture upon "Some Experimental Observations Relative to the Surgery of the Nervous System."

Meschianza for the McKinley Memorial Hospital.—On Monday, November 11, at the Academy of Music, Philadelphia, the following speeches were made by physicians: "The Reasons of the Entertainment," Judge William N. Ashman; "The William McKinley Hospital Association," Dr. John Madison Taylor; "The Needs of a Pay Hospital for Contagious Diseases," Dr. James Tyson; "The Care of Contagious Diseases in Special Hospital," Dr. James C. Wilson; "Contagious Diseases and the State," Dr. John V. Shoemaker. Mayor Ashbridge then declared the Meschianza open, and Professor Ives and Dr. Jay F. Schamberg gave a magic lantern display.

Smallpox in Philadelphia.—More new cases of smallpox were reported for the week ending November 9th than for any similar period during the year. Seventy-two persons were prostrated and there were eight deaths. Since January 1 there have been, to date, 559 cases, of which seventy-eight resulted fatally. Of the 481 persons who survived, 262 have been cured, while 219 are confined to their homes or in the Municipal Hospital. Over 200 cases are now in the Municipal Hospital, the largest number at any one time in the present epidemic. The completed portion of the new frame building now being erected on the hospital grounds for smallpox cases is being utilized. The wings will be finished this week. Success is crowning the labors of Dr. George MacLeod in the smallpox district of Bryn Mawr. The spread of the disease has been checked. Smallpox made its first appearance in Bryn Mawr College was attacked. It was discovered that the negro settlement known as Whitehall was full of the disease. A Board of Health was formed at once, and under the direction of Dr. Chrystie those who showed marked symptoms were sent to the Municipal Hospital. At last the hospital refused admittance to any more patients from Montgomery County. The Bryn Mawr Hospital had no contagious ward, and a serious problem confronted the community. At this crisis, Dr. MacLeod volunteered to take charge in

the settlement. His offer was accepted and the settlement was strictly quarantined. This measure proved effective. No more cases have been reported and no deaths among those under Dr. MacLeod's charge have occurred. Of the new cases reported two were in Germantown and one in Olney. One case is reported from Camden, Del., in a lady who had just come from Philadelphia. The schools there have been closed on this account.

St. Timothy's Hospital Annex.—The \$85,000 men's ward annex to St. Timothy's Hospital will be dedicated Saturday, November 16th. The annex was erected as a memorial to Percival Roberts by his widow, Eleanor Williamson Roberts. It is one of the most complete hospital buildings in the United States, having all the latest improvements. The new building is of brick, four stories high, and will accommodate fifty patients.

Opponents of a Hospital Defeated.—An injunction asked by a number of West End citizens to restrain the Norristown Town Council from establishing an emergency hospital at old Oak View Park was refused. Among others who opposed the place was Dr. D. D. Richardson, of the State Hospital for the Insane, because the emergency hospital is within a quarter of a mile of that institution.

Diphtheria is reported in Hazleton Pa. It is feared that it will wipe out a family at Quakake, a few miles south of Hazleton. Within a month five children have died and the mother succumbed. Three other children are suffering, while the father and one son have been the only ones thus far to escape. The public schools have reopened at Athens, Pa. after having been closed two weeks on account of the epidemic of diphtheria.

Bucks County Medical Society.—At the annual meeting of the Bucks County Medical Society held at Doylestown, November 6, these officers were elected for the ensuing year: president, Dr. H. A. Hilyer of Penn's Park; vice-presidents, Drs. Henry Lovett of Langhorne and A. E. Fretz of Sellersville; secretary and treasurer Dr. F. A. Myers, of Blooming Glen; Board of Censors Drs. G. M. Grim of Ottsville; W. R. Stavely, of Lahaska, and William R. Cooper, of Point Pleasant.

Death of Dr. Orr.—News of the death of Dr. John C. Orr, at Mindanao, on September 12, has been confirmed by a telegram to the parents, Mr. and Mrs. John R. Orr, of Chambersburg. Dr. Orr was 31 years old, and a graduate of the University of Pennsylvania. He was attached to the Twenty-third Infantry, at Turcuran, Mindanao.

NEW YORK AND NEW JERSEY.

Tuberculosis Theory Tested.—Dr. George D. Barney, a physician of Brooklyn, with the assistance of a young woman who volunteered to become the subject of an experiment has, he says, started out to demonstrate the truth or falsity of Professor Koch's theory that tuberculosis germs cannot be communicated from a cow to a human being. His statements have been called to the attention of the Brooklyn office of the Health Department, which will investigate his assertion that he has injected tuberculosis germs into the young woman's neck. The matter will be laid before the counsel of the Health Board and, if he shall so advise, steps will be taken to bring the matter before the Kings county District Attorney, if it is found that Dr. Barney has done as asserted. According to the statement of the physician, the young woman, who was under treatment for some minor ailment, volunteered to permit him to inject the bacteria from the cow into her neck. The doctor describes her as an educated woman, whose parents are wealthy, and who had no other motive in offering herself as a possible sacrifice on the altar of science than the good of humanity. The operation, he says, was performed Saturday evening, November 9th, the culture from the cow being placed under the skin on each side of the neck, just above the clavicle. He said no effects had yet appeared. The cow, which was imported from Canada, had shown typical signs of tuberculosis after having been inoculated with human tubercle bacilli.

Damages for the Death of a Physician.—The second appellate division of the Supreme Court of New York holds, in the case of Ericius vs. the Brooklyn Heights Railroad Co., that it cannot be said that an award of \$15,000 damages is excessive for causing the death, through negligence, of a physician about fifty years old, who was earn-

ing, in the practice of his profession, \$175 a month.—*Journal of the A. M. I.*

No Skene Hospital.—Supreme Court Justice Maddox in Brooklyn has granted an order dissolving the Skene Hospital for Self-Supporting Women. The petition says that \$300,000 was necessary to carry out the project and that only \$23,000 was subscribed, of which only \$3,261 was paid. The hospital was to have been erected as a memorial to the late Dr. A. J. C. Skene. The order directs the distribution of the \$3,261 among the contributors.

Grown to a Colossus Within Thirty Days.—A farmer living near Cokesbury, N. J., within thirty days has changed from a man weighing about one hundred and forty pounds to one weighing almost four hundred pounds. His weight increases four to six pounds daily. He is sixty-five years of age, and up to last summer was strong and vigorous. While making hay he was sunstruck, but in two weeks appeared to have recovered, and was about as usual. A month ago, dropsy set in, and he began to gain weight at first slowly, and then very rapidly. He is not expected to live much longer.

NEW ENGLAND.

Boston Smallpox Situation.—There were 22 cases of smallpox reported by the Boston Board of Health for the week ending November 9th, three of which were fatal. This makes 115 cases reported since last July. The chairman of the board said that the hospital in use has a capacity of 50 or 60 patients. This hospital is well fitted up, and possesses the best means for the comfort and well-being of patients. All patients able to be taken to the hospital are taken in. It is a matter of only a few hours from the time a case is known until it is comfortably situated in the hospital, that the house from which the case is taken and all infected things therein are disinfected, and all persons known, or supposed to be exposed, vaccinated and watched until the stage of incubation for this disease has passed. Cases are constantly occurring as a result of exposure to unrecognized and unreported cases of smallpox. There can be no question as to the importance of immediate vaccination for all who have not yet had this duty performed, and that revaccination is equally necessary for most people over 10 years of age who have not recently been vaccinated. Offices for free vaccination are open daily.

An X-Ray Lawsuit.—A physician of Willimantic, Conn., has brought suit against a Boston company, to recover damages for burns received while testing an X-ray machine sold to him by the defendants. Expert testimony has brought forth remarkably contradictory opinions. The majority of the witnesses believe that static electricity, reasonably used, is perfectly harmless. The suit has not yet been settled. The physician was severely burned, and his practice has suffered since.

The Floating Hospital.—The Boston Floating Hospital, incorporated September 23, held its first annual meeting November 5th at Young's Hotel. Two contributions toward the endowment fund have already been received, \$5000 from a Somerville lady, and \$500 representing the "Caroline P. Adams memorial." About \$2500 has also been received for the new boat fund. The need of a new hospital boat is imperative.

A Scientific Man Honored.—Alpheus H. Packard, M. D., Ph. D., LL. D., was tendered a reception at the University Club, Providence, R. I., in recognition of the honors recently conferred upon him by scientific societies of England and America. Speeches were made and a poem pertaining to the occasion read.

For a New Hospital.—Dr. Cogswell, formerly port physician of Boston, founder and superintendent of the great hospital system at Long Island, has purchased the valuable estate in the Middlesex Fells Reservation, known as the Langwood Hotel, for the purpose of establishing a general hospital. This magnificent country place embraces 10 acres of cleared and wood lands, located directly in the heart of the reservation of 3500 acres of hills, groves, and uplands, all of a wonderfully wild and picturesque character, including that superb sheet of water known as Spot Pond. The hospital will be known as Middlesex Hall, and any reputable physician may send his patients there. It is located about five miles from the center of Boston.

Smallpox in New England.—Beside the cases of smallpox in Boston 44 cases are reported at St. John, N. B. Great care is being exercised in the examination of all passengers arriving at Portland, Me., by boat, or at Vanceboro, Me., by rail. It is possible that some of the cases discovered in Boston brought the infection from St. John.

WESTERN STATES.

Cars to Isolate Consumptives.—The isolation of consumptives on railroad trains is planned in Chicago. Railroad men admit the present danger of the spread of disease and refer the matter to the Pullman Company, which controls the sleeping cars. The plan for reform was promulgated as the result of numerous protests against the peril in journeying with men afflicted with phthisis. Separate coaches should be used. A communication was read from the Travelers' Protective Association objecting to the practice of allowing sufferers from phthisis to occupy space in sleeping cars and coaches with persons not afflicted. Consumptives, they suggested, should be isolated so far as possible by the railroads, and not allowed in cars where they mix with other passengers. The evil is largely confined to trains going to Colorado, New Mexico and Arizona, where the mild climate is sought, and all persons traveling thither from Eastern points are exposed. Recently a proposition was made to officers of one of the roads operating out of Chicago to establish a consumptive cure in the pine woods of Northern Wisconsin. The officers of the road declined to encourage the project on the ground that the transportation of diseased persons to and from the camp would be objectionable to other passengers, and would tend to hurt the business.

The Ohio Valley Medical Association held its sixth meeting on November 11 and 12, 1901, at Henderson, Ky.

St. Francis' Hospital, Peoria, Ill.—The new St. Francis' Hospital, occupying a commanding position on the East Bluff, was opened to the public October 10th, and thousands passed through the five-story stone fireproof structure, erected at a cost of \$115,000. It is under the direction of the Sisters of the Order of St. Francis. The interior is finished in quarter-sawn red oak, with the finest operating-room, entirely of marble, in the West. The hospital received a large number of valuable gifts on its opening day, and its formal dedication by Bishop Spaulding will take place at a later date.

Michigan Board of Health.—The next general conference of health officials in Michigan will be held in Ann Arbor, Michigan, November 21 and 22, 1901. The attendance of a number of officials is expected.

Fire in a Smallpox Hospital.—Eighteen smallpox patients, confined in the City Detention Hospital, Des Moines, Iowa, were forced to flee for their lives from the burning structure, November 7th. Policemen, fearful of acquiring contagion, were at first slow to seize the escaping patients. Firemen, having an equal dread of the disease, were also chary about approaching the flames, but all conquered their fear when it was seen that the lives of the unfortunates were in danger. Eventually the police corralled the inmates of the pesthouse and kept them under guard on a vacant lot a half block away. Three of the patients were suffering so severely from the disease that they were unable to walk, and it was due to the heroism of fellow-sufferers who carried them out of the flames, that these three were rescued. The wind was blowing and the thermometer stood below freezing. It is feared that the exposure will result in several deaths. Efforts to induce neighbors to throw open their homes to the diseased persons were unavailing. As a last resort a squad of policemen, armed with hatchets and saws, set to work preparing huts for temporary shelter. Neighboring property owners threaten injunction proceedings.

SOUTHERN STATES.

Medical Society of Virginia.—At the thirty-second annual meeting of the Medical Society of Virginia, held November 5-7, the following officers were elected for the ensuing year: President, Dr. R. S. Martin, Chatham; vice-presidents, Drs. L. Lankford, Norfolk, R. I. Griffin, Bosle City, and S. W. Dickinson, Marion; secretary, Dr. L. B. Edwards, Richmond; treasurer, Dr. R. T. Styll, Newport

News. Dr. J. It. Gildersleeve, the retiring president, and Dr. T. D. Crothers of Hartford, Conn., were elected honorary fellows. The executive committee elected were Drs. Upshur, Hoge and Irving of Richmond, Claiborne of Petersburg, and Culpepper, of Portsmouth. The delegates to the American Medical Association to serve for two years were Drs. Gildersleeve and Edwards.

Appointment.—The news has come from New Orleans that Dr. Gordon King has recently been appointed professor of otology, rhinology, and laryngology in the Polyclinic School of Medicine.

The Southern Surgical and Gynecological Association held its fourteenth annual session, November 12, 13 and 14, 1901, at Richmond, Va.

The Army Medical School has begun its sixth annual session in the Army Medical Museum, Washington, D. C. Nineteen student officers are to take a five months' course of study in military surgery, hygiene and medicine, microscopy, hospital corps drill and first aid.

The Brazos Valley Medical Association met in Calvert, Texas, November 12 and 13, 1901.

Memorial Hospital, Richmond, Va.—The corner-stone of the Memorial Hospital of Richmond was laid on November 5th in the presence of a number of physicians who will be connected with the institution. The walls of the hospital are going up rapidly and the contract calls for its completion next July.

The Maryland State Medical Society will hold its annual meeting in Baltimore, November 19th.

More About Mosquitoes.—Dr. G. M. Corput, assistant surgeon, U. S. M. H. S., has found that the china ball tree prevents the breeding of mosquitoes to a great extent. While he publishes only the results of his preliminary experiments, this result seems plain. He hung cans of fresh water in thickets of oak, pine, palmetto and china ball trees in Georgia. In all except the china ball trees the mosquitoes bred readily. He expects to carry his investigations further.

MISCELLANY.

Tonkin Medical School.—The governor-general of Indo-China has decided to establish a medical school for the natives at Hanoi. He will erect a hospital for natives, and will appoint two professors, an army surgeon and a physician.

International Sanitary Congress.—At the last Pan-American Medical Congress it was decided to hold a sanitary congress in Havana this year. Announcement has just been made that the congress will be held February 15, 1902. It is proposed to meet once every three years to discuss international sanitation. The prime movers in the organization of this congress were Drs. Wilde, of Argentine Republic, and Wyman, of the United States.

Molokai Leper Colony.—There are now 909 lepers and 164 clean persons at the Molokai leper settlement in Hawaii, according to a report received from Chief Quarantine Officer Cofer, in charge of the Marine Hospital work in Hawaii. All these are housed, fed, clothed and governed for \$80,000 a year. He praises the hopeful and cheerful way in which these people resign themselves to their fate and points out that such contentment can thrive only on a comfortable mode of life and good treatment. He made careful inquiries as to the chances of infection of the clean people working among the lepers. The general opinion was that in time they would become lepers. In the last ten years, however, only ten clean residents have become lepers. The Board of Health has initiated a new system for preventing the lepers and their relatives and friends from embracing and kissing each other, by marching the visitors immediately from the steamer landing to a corral with a double fence. The friends are compelled to remain inside this inclosure and lepers gather around and talk through the bars. Visitors are permitted at any time under this system, instead of only once a year, as formerly. The results of known exposure to leprosy show an uncertainty as to the chances of individual infection, which makes the disease one of the most difficult to operate against. Women are said to be less liable to it than men. The oldest three patients at the settlement arrived in 1874, 1875 and 1879, respectively. The recruits to the settlement each year during the last decade range from 132 in 1890 to 85 in 1900, showing a

gradual decrease, despite the fact that the hunt for lepers through the islands never before has been so vigorous.

Cremation.—The time required to heat a furnace for the purpose of cremation is generally three hours. The degree of heat of a furnace for cremation purposes is about 2500° Fahrenheit. The body is reduced to ashes in from an hour and a half to two hours. The coffin, with the exception of the glass and trimmings, is incinerated with the body, except in the case of metallic caskets, then the body is removed from the casket. There is no odor while the body is being consumed. When the casket containing the body is placed on the carriage just before being sent into the furnace it is covered with an alum-soaked cloth, so that it may not catch fire while being transferred to the furnace. Within three minutes after the casket and body has been placed in the furnace the whole becomes a mass of flames and then a mass of cinders at the end of the time stated.

Smallpox a Foe to the Insurgents.—The following report has been received under date of October 21 from Captain Thomas Perry, of the battleship Iowa, which has been lying at Panama watching the progress of affairs in that quarter. "I have the honor to report that at this moment activities are taking place on the part of the insurgents who have until recently been in the neighborhood of Chorrera. It is said this movement on the part of the insurgents had been forced upon them before they were ready by the prevalence of smallpox in their camp at Chorrera, the disease so decimating their numbers that they were obliged to go to save their entire force from becoming decimated."

Death of Dr. Kerr.—On August 10th, in Canton, China, Dr. John G. Kerr, who had been a medical missionary for nearly half a century, died of dysentery. For forty years he was connected with the Canton hospital, but left a few years ago to take charge of an insane asylum which he established in Canton. His surgical work was renowned, but one surgeon in the world having surpassed him in the number of operations performed for stone in the bladder.

Obituary.—Dr. J. N. Adkins, at Lampasas, Tex., October 6, aged 68 years—Dr. James J. Flynn, at Milwaukee, Wis., November 2—Dr. Hiram Tuttle, at Tacoma, Wash., October 9—Dr. C. J. B. Hirsch, at Audubon, Minn., October 16—Dr. Ralph E. W. Lerch, at Mt. Gilead, Ohio, October 8, aged 27 years—Dr. Lorenzo Firmin, at Findlay, Ohio, October 13, aged 94 years—Dr. H. K. Hershisser, at Tiffin, Ohio, October 8, aged 70 years—Dr. Frederick Loeber, at New Orleans, La., October 18, aged 62 years—Dr. John P. Bishop, at Charlestown, W. Va., November 5, aged 42 years—Dr. E. L. Diefenderfer, at Milwaukee, Wis., October 27, aged 62 years—Dr. John D. Dunning, at Webster, N. Y., October 27, aged 75 years—Dr. Dennis W. Porter, at Decatur, Ill., October 23—Dr. Peter Hewetson, at Amanda, Ohio, October 26, aged 79 years—Dr. R. D. Blackmore, Iowa City, Iowa, October 26, aged 27 years—Dr. Robert T. Bush, at Gallatin, Tenn., October 27, aged 65 years—Dr. C. M. Spalter, at Long Island Sound, N. Y., November 7 aged 27 years—Dr. Samuel S. Gnile, Fond du Lac, Wis., November 8, aged 74 years—Dr. George W. Burke, at Newcastle, Ind., recently, aged 70 years—Dr. Robert S. Hamilton, at Staunton, Va., November 9—Dr. C. H. Orton, at Chicago, Ill., November 8, aged 84 years.

GREAT BRITAIN, ETC.

The Mortality of Children in South Africa.—The English newspapers show that during September, while only 447 adults died in the Boer refugee camps in South Africa, the deaths of 1964 children are reported. Great Britain seems to be killing so many children in these detention camps that the country can only be repopulated by immigration. This high mortality among children occurs in spite of all that is done by the English officers to alleviate the condition of the Boer women and children.

Country Hospital for Children.—Funds are now being raised in Liverpool for the erection of a Country Hospital for the Chronic Diseases of Children. Mr. T. S. Timmis has contributed \$5,000.

The Sixth Intercolonial Medical Congress of Australasia will be held at Hobart, Tasmania, February 17 to 22, 1902. There will be general discussion on cancer. "Intercolon-

ial" is no longer applicable, and the name will probably be changed.

The Plague in England.—From Glasgow and Liverpool comes the news that bubonic plague has been stamped out. The last cases of the disease reported reached the hospital November 1st. There has, however, been a suspicious death upon a steamship at Hull. Indications seem to point to the plague as the cause of death.

Another Bequest to the Glasgow Hospitals.—By the will of the late Mrs. Janet Rodger, \$40,000 has been bequeathed to the various Glasgow hospitals.

The Vegetarian Society.—At the 54th annual conference of the Vegetarian Society, held in Manchester, October 21, it was shown that the society had made but little headway during the 53 years of its existence. There were but 59 members received last year. The statement was made that a large number of members had died during the year, surely an unusual result when one considers the claims made for vegetarianism.

The Plague in Bombay.—In spite of the hot weather there has been a continued increase in the number of deaths from plague throughout Bombay early in September. This increase was probably due to the onset of the rainy season. The only other increase noted in India was in Mysore.

Smallpox in London.—The present epidemic, instead of decreasing, has suddenly shown a marked increase, 79 cases having been reported in three days. The centres of infection have become widespread throughout London, and vaccination and revaccination are being widely practiced. This is, however, more among the wealthy than among the poor. The present invasion will probably educate the public upon the value and necessity of vaccination.

The John W. Garrett International Fellowship.—A fellowship has been founded by William Johnston in connection with University College, Liverpool, in memory of the late John W. Garrett, of Baltimore, with the title of the "John W. Garrett International Fellowship in Pathology and Physiology."

Obituary.—On October 21, John Halliday, a graduate of Guy's Hospital, one of the oldest physicians in Leeds, died of apoplexy. He had practiced in Leeds for over half a century.—On the same day Dr. Alfred Alpin, superintendent of the Notts County Asylum, died from heart disease, aged 47 years. He was a graduate of University College and at one time lectured on physiology at Nottingham University.—At Helston, Cornwall, B. C. Kendall died October 24th, aged 36 years. He was a graduate of the Bristol Medical School and Guy's Hospital.—Dr. W. H. Caldwell, of Coleraine, Ulster, a graduate of the Royal University of Ireland, died from hemiplegia, October 25th.

CONTINENTAL EUROPE.

University Notes.—Frankfort: The sum of 500,000 marks has been given to the city of Frankfort-on-the-Main for research work upon the etiology of cancer. Prof. Ehrlich has undertaken the work, with the assistance of Dr. Weldenreich of Strassburg.—Goettingen: The new Polyclinic for Mental and Nervous Diseases has just been opened, under the directorship of Prof. Cramer.—Leipsic: The widow of Dr. Puschmann, formerly professor of the history of medicine in the University of Vienna, left, upon her death, over \$20,000 to the University of Leipsic.—Freiburg: Dr. Bäumler, professor of medicine at Freiburg University celebrated the completion of 25 years in practice on October 31, 1901: Munich: Dr. von Voit, the renowned physiologist, celebrated his 70th birthday on October 31, 1901.—Liege: Dr. Schiffrers has just been appointed professor of laryngology, otology and rhinology.—Heidelberg: A medallion in memory of Dr. W. Kühne, formerly director of the Physiological Institute, was unveiled October 20th in the presence of the friends, colleagues and former students of the late professor.—Tomsk: Dr. A. Mysch has been appointed professor of surgery.—Vienna: Dr. Alois Monti, director of the Polyclinic Hospital, has been put in charge temporarily of the clinic for the diseases of children. Dr. Anton Drasche and Dr. Josef Weinlechner, professors in the Medical School of the University of Vienna have been retired on account of old age. They were tendered a farewell reception in their departments of the general hospital.

Plague in Russia.—A cablegram was received November 11 at the office of the surgeon general of the Marine Hospital service, saying that plague had appeared at Odessa, Russia.

Congress of Russian Naturalists and Physicians.—The eleventh Congress of Russian Naturalists and Physicians will be held in St. Petersburg, December 20-30. But three sections are concerned in medical subjects, one for anatomy and physiology, one for scientific medicine, and one for hygiene. The committee in charge consists of Professors Menschutkin, president; Inostranzew, vice-president; Borgmann and Schewjakow, executive committee.

The Paris Morgue.—This low building is situated behind the Cathedral of Notre Dame, directly upon the Seine where its two branches unite. The main room contains glass show cases in which the bodies lie while awaiting identification. They rest upon stone tables, while decomposition is prevented by artificial ice, made from calcium chloride and ammonia. To the right of this show room are the offices of the director. There are many photographs of the unidentified dead in the show room, and back of it is a small room, its walls covered with drawers in which repose more unidentified bodies, also kept cold by artificial ice. Next is a room containing a pile of coffins of all sizes; then comes the amphitheatre where the demonstrations in medical jurisprudence are given by Dr. Brouardel and his assistants. There are some small rooms, one for funerals, another where criminals are confronted with the bodies of their victims in the presence of the authorities. Formerly a reward was offered for bodies drawn out of the water; but this was almost an inducement against life saving. Now 25 francs are given for each person rescued from drowning, while only 15 francs are paid for a dead body brought to the morgue. Morgue is derived from an old French word meaning "countenance hautaine," since it was the custom in former times to keep all prisoners outside the prison for some time, that their countenances might be studied for later recognition. Throughout this one story building is heard the swish of the waters of the Seine below.

Inventor's Peace Prize.—Under the terms of the will of Alfred Nobel, the Swedish engineer and chemist who first applied nitro-glycerine, dynamite and blasting gelatine as explosive agents, who died in 1896, \$2,000,000 of his fortune of \$10,000,000 was left as a fund to provide prizes for the advancement of science. The interest on the \$2,000,000 was divided into five annual prizes. Prizes Nos. 1, 2 and 3 are to be awarded to the persons making the most important discoveries in physics, chemistry, physiology or medicine. Prize No. 4 is to be given to the person making the best literary contribution upon the subject of physiology or medicine. Prize No. 5 will be awarded to any person who has achieved the most or done the best thing looking to the promotion of the cause of peace throughout the world. These prizes are open to any person in any part of the world. Although not officially announced at Christiania it is regarded as assured that Dr. Henri Dumant, the Swiss physician who was recommended by the Swedish Riksdag to the committee intrusted with Nobel's annual prize for the encouragement of peace and arbitration, will be awarded that prize this year.

Alcoholism.—A French physician, Dr. Bourneville, reports that among 2072 boys and 482 girls suffering from idiocy, imbecility and various paralyses, there were 40 per cent. in whose cases alcoholism in one of the parents or both was found.

Scarlet Fever in Bremen.—Almost four hundred cases of scarlet fever have been reported in Bremen during August and September, with over 50 deaths. Half of the patients that died were between the ages of one and five years, and only four were over 20 years old. The epidemic is now well under control.

Obituary.—Dr. George Näher died of paralysis of the heart suddenly on October 24th in Munich.—Dr. T. Ynnez y Font, professor of medical jurisprudence in Madrid.—Dr. J. H. Chievitz, professor of anatomy in Copenhagen.—Dr. J. Grosser, founder and editor of the *Deutsche Medizinische Zeitung*, died in Prenzlau, October 26, aged 66 years.—Dr. Julius Cesar Häntzsche, whose death in his 75th year is reported, was formerly physician to the Russian embassy in Persia.

1.—See abstract from *Lancet*, October 26, 1901.

2.—Delépine obtained from the Manchester Consumption Hospital 6 specimens of human tuberculous sputum containing bacilli belonging to the following types: (1) long, slender, showing typical metachromatism; (2) thick, staining almost uniformly; (3) short, in clumps; (4) short, staining badly. With this mixed sputum the author experimented on four calves. One was inoculated directly into the lung, the second was inoculated subcutaneously, the third was inoculated into the peritoneum, and to the fourth milk was given containing 10 times as much sputum as the others had received by inoculation in two meals. The calf that was inoculated into the lung died on the sixth day; it was found to have generalized tuberculosis, not due to the inoculation. The calf that was inoculated under the skin of the leg, died on the sixth day. There was marked enlargement of a gland at a distance of 5 inches from the seat of inoculation, but no other traces of tuberculosis. Living and virulent tubercle bacilli were found in the affected gland. The calf that was given 50 cc. of mixed sputum with its food in one day, died 26 days after the ingestion of the tuberculous material. There was no trace of tuberculosis in any organ except the glands connected with the alimentary canal. Virulent tubercle bacilli were found in the esophageal glands. The calf that was inoculated in the peritoneal cavity gave a definite tuberculin reaction 68 days after the inoculation. The post-mortem examination was made 70 days after the inoculation and showed marked tuberculosis of the peritoneum, extending gradually to the pleura and the pericardium. No other organ was affected with tuberculosis except a few of the lymph-nodes connected with the peritoneum. Therefore, of the 4 calves experimented upon only 2 survived long enough to allow definite results to be obtained, and these 2 calves had contracted tuberculosis

as the result of ingestion of or peritoneal infection with human tuberculous sputum. [J. M. S.]

3.—See abstract from *Lancet*, October 26, 1901.

4.—Kelson reports a case of primary chancre of the tonsil. [J. M. S.]

6.—Toxic action is by far the most important factor in the pathogenesis of insanity. Robertson further says that the large majority of cases of insanity are not primarily diseases of the brain at all, but are dependent upon the action of toxins derived from elsewhere, that affect the functional activity of the cortical nerve cells by disordering their metabolism, and often permanently damaging or even destroying many of them. The common view that the mental disease is the primary condition, and that any accompanying bodily disease is secondary is, in general, founded upon an erroneous conception of what is taking place. [J. M. S.]

7.—Sympathy is one of the first conditions of success in the treatment of neurasthenia, and one of the chief causes of failure is the want of it. Patience, perseverance, firmness and tact are also essential factors. Hysteria or neuromimesis is distinctly a disease of the subconscious mind, of unconscious suggestion; and it is in this very fact of its unconscious nature that it differs from all forms of malingering, which always imply conscious fraud. Power of attention to details is also an element of importance. Cases of nerve irritation or exhaustion dependent upon external causes or upon physical lesions are purely physical. On the other hand, cases of neuromimesis contain a distinct mental element. The point to determine in cases of neurasthenia is the stage and the character of the disease; as to whether the nerve centers are in a state of irritation or of exhaustion or of both. If the cause of some of the symptoms remains obscure, carefully consider the question of sexual agencies, both physical and mental, natural and unnatural, for the extent to which this latter is a factor is little known to many physicians. With neurasthenics, east-iron systems of treatment stand condemned in theory and in practice. Neurasthenics cannot, as a rule, be cured in their own homes. Hypnotism, however, is of doubtful benefit in the majority of neurotic cases. [J. M. S.]

10.—In a number of cases of insanity, Turner found alterations in the pyramidal and giant nerve cells of the cortex that were identical with those produced in the hypoglossal and anterior cornual cells of animals by severing their axis cylinders. Except in traumatic cases, in which the axis cylinder has been separated from the cell, he only met with this alteration in certain cases of melancholia, of dementia following melancholia, in a few cases of dementia of alcoholic origin that rapidly terminated fatally, or in some cases of imbecility. Observations on the distribution of this change appear to indicate that the cause that brings it about is not a general one, operating on all parts of the nervous system. The change early affects the afferent cells, notably those of Clarke's column; and although, at first, the efferent tracts of the cord are unaffected, ultimately they begin to degenerate, and apparently this degeneration starts in those outlying parts of the cell farthest removed from its body. The author is of the opinion that the conditions of the pyramidal and giant cells found in these cases of melancholia are brought about by depriving them of the afferent impulses that normally pass to them. [J. M. S.]

12.—Feeble-minded children are estimated at about 1% of the school children in Great Britain. In making a diagnosis of a case said to be feeble-minded, Warner looks for the presence of signs of brain defect as apart from the fact of mere mental dulness and ignorance. As points in making a physical diagnosis we may look to (1) developmental and physiognomical signs, (2) nerve signs and indications of the general characters of brain action and (3) conditions of the body, the organs of special sense and general health. In commencing the treatment of a feeble-minded child we aim at removing the abnormal nerve signs in detail, and, at the same time, at improving the normal character of spontaneity and controllability. Andriezen referred to 4 points in the discussion: (1) The difficulty of diagnosis of feeble-mindedness in an infant of 12 months or less, the chief manifestations being the lack of variety and spontaneity in its movements and inability

to imitate; (2) the importance of development of the kinesthetic life by manual and industrial training, which seemed to reform young criminals with defective intellect very effectually, and had also proved useful in idiot asylums; (3) the fact that imitation might be the cause of faulty habits and "tic" in children, and that cure could in some cases be effected by removing the child from the source of imitation; and (4) the necessity of further developing the plan of classification of the lunatic and the degenerate, and especially the need of institutions for moral imbeciles and allied forms of degenerative and impulsive insanity which were not fit to be at large. Angell said that there are 2 types of stigmata, the anatomical and physiological. A single anatomical defect, such as a malformed ear or a highly arched palate, is of little importance, but the association of such stigmata is highly significant of defective cerebral development. [J. M. S.]

13. Ulceration of some parts of the intestines is acknowledged to be by no means an uncommon thing in asylums, but it is quite independent of overcrowding, and Shaw does not think that it depends either on the food, or the sewage farms, on the habits of the patients, or always on the presence of a bacillus of a particular type. He believes that there is a degeneration of the mucous coats of the intestine due to nerve degeneration, and that as ulcer of the stomach occurs without apparent cause, so we may have ulceration of the intestines without its being septic in origin. Ulceration in the intestine may occur without diarrhea or dysentery, and these latter may be present when there is no ulceration in any part of the intestinal canal. Diarrhea is, as a rule, more common in the outside world than in asylums. It appears that there is such a thing as *asylum dysentery* or *diarrhea*; but the author is of the opinion that all cases of colitis, with or without ulceration, are not primarily bacterial in origin. He does not deny that bacteria are secondarily present, and that then the cases may become infectious if the discharges are not properly treated and the nursing is insufficient; but he contends that there will be in asylums and among the insane a condition of degeneration, attended or not by diarrhea or dysentery, that is liable to occur at any time, especially in the more degraded and chronic types of insanity, which no amount of care, either in nursing, diet or general hygiene, can prevent. [J. M. S.]

LANCET.

October 26, 1901.

1. Note on the Result Obtained by Anti-Typhoid Inoculation in the Case of an Epidemic of Typhoid Fever which occurred in the Richmond Asylum, Dublin.
A. E. WRIGHT.
2. The Effects of Lead upon the Lead-Workers in the Staffordshire Potteries.

H. WRIGHTON.

1.—Wright gives an account of the results obtained by anti-typhoid inoculation in the case of an epidemic of typhoid fever which occurred in the Richmond Asylum, in Dublin. The first case of typhoid fever in this epidemic was observed on August 7, 1900. Cases developed amongst the inmates and nursing staff; toward the end of December 54 cases of typhoid fever had occurred. Soon after the beginning of the epidemic anti-typhoid vaccination was begun and a total of 511 persons were inoculated. Only individuals under the age of 55 were subjected to the inoculation and none of the nursing staff underwent the operation; .75 cubic centimeters constituted the dose. On September 26, 29 cases of typhoid fever had occurred in the uninoculated and seven cases of fever had developed in the inoculated individuals. An account of the histories of the cases which had developed in the inoculated individ-

uals is given. In the brief summary he states that "analysis has shown that of the inoculated persons attacked by the disease the first had certainly developed the fever before inoculation; the second had almost certainly contracted the infection before inoculation; and the third and sixth had also probably contracted it before inoculation. In the case of the fourth and seventh patients, if the infection was, as would seem probable, contracted subsequently to inoculation, it must have been contracted immediately afterwards, while the patients were still suffering from the effects of the operation. Thus the fifth patient would appear to have been the only one among the seven inoculated patients attacked who contracted the infection after the clinical symptoms due to the operation had passed off." Out of a body of 655 susceptible individuals consisting in part of inoculated and uninoculated subjects, six cases of typhoid fever occurred in the inoculated and 29 in the uninoculated. On Nov. 30th, the date of the completion of the inoculations, 504 individuals had been inoculated and in this group no case developed between this date (Nov. 30) and December 24, when the last case of enteric fever occurred. In the same period between November 30th and December 24, 114 persons were not subjected to inoculation, and five from this group contracted the disease. The writer states that these facts bring out in a striking manner the comparative immunity of the inoculated. [F. J. K.]

2.—Shufflebotham gives an account of the effects of lead upon the lead-workers in the Staffordshire Potteries. He has made a systematic examination of the workers employed in 13 factories in Staffordshire potteries in order to determine the state of health of the lead-workers. The total number of people employed in these factories is between 6000 and 7000, out of this number 528 are engaged in lead processes. In his article he has inserted a number of tables (1) showing diseases affecting some of the individuals; (2nd) an extensive table which deals with the lead lines upon the gums; (3rd) one showing the number of pregnancies in lead-workers' wives who have never aborted; (4th) another showing the number of pregnancies and miscarriages in lead-workers' wives who have aborted; (5th) another showing the number of pregnancies in women working in lead; (6th) lastly a table showing the number of pregnancies and miscarriages in women working in lead who have aborted. The author reached the following conclusions which are quoted in substance: "1. That of the 527 lead-workers I only met with one case of lead-poisoning. 2. That individual symptoms, which at first sight might have been attributed to lead poisoning, were found upon closer examination to be due to other causes. 3. That the health record of the lead-workers was excellent (the complaints I have mentioned are for the most part only minor ailments). Of 348 men, 198 have not lost a single day's work through ill-health from any cause whatever since they commenced to work in lead, and the same may be said of 90 out of 124 single women; 26 out of 55 married women have only been absent through confinements. 4. That the general condition of the work people was good and would compare favorably with that of a like number of workers in any average healthy trade. 5. That the 91 operatives who had worked in lead for over 20 years were not suffering from any ill-effects from their employment, although they had worked for years under practically no regulations. 6. That it must always be remembered that lead-workers are subject to the common ailments of life just in the same way as other people." [F. J. K.]

3.—Campbell Thomson discusses "dilatation of the stomach with illustrative cases. During the past three years this author has observed four cases of dilatation of the stomach, death being due to this condition. The diagnosis was confirmed by post-mortem examination in each case, and he believes that while this condition is an uncommon one, it is more frequent than generally supposed. He has

also collected six cases from literature. He states that there are various degrees of severity of this condition, slighter forms being met with not infrequently in the acute specific fever. Emphasis is laid upon the statement that the treatment of the recorded cases seems to have been of no avail. The introduction of the stomach tube was followed by no permanent improvement. Hypodermic injections of strychnia lessened the tendency to collapse, and feeding per rectum was always practiced. He remarks that perhaps dilatation of the stomach is a local manifestation of a total collapse and that the condition may be more common than is generally supposed. [P. J. K.]

4.—In reporting a number of cases of **acute retropharyngeal abscess** of infants S. Vere Pearson discusses the diagnosis and treatment of this condition. It is one which is not as infrequent as is generally supposed. Reference is made to several cases in which incorrect diagnosis has been made, the condition being mistaken for laryngeal diphtheria. The youngest patient which the author has seen suffering from this condition was seven weeks old. If the condition is thought of, and careful examination made, a diagnosis is not difficult. The condition is usually found in patients under two years of age. The voice becomes muffled, there is difficulty in nursing, with apparent pain on swallowing; the child is restless, has loss of appetite, and not infrequently there is a purulent nasal discharge either preceding or accompanying the condition. Considerable obstruction to respiration is common. The presence of tender and enlarged glands in the cervical region tends to make one think of laryngeal diphtheria. A careful examination of the neck will show one side fuller than the other, and an inspection of the pharynx will show the tonsil more prominent on one side than on the other, and the postpharyngeal wall will appear to be pushed slightly forwards. A visual examination of the throat is difficult and the best way of locating the abscess is by palpation with the forefinger. Sometimes it is difficult to obtain fluctuation. The cause of the abscess is an acute post-pharyngeal suppurative adenitis. The association of a purulent nasal discharge is interesting in this connection. The form of abscess described by the author is of course quite distinct from the chronic retropharyngeal abscesses due to spinal caries. The abscess should always be opened through the neck behind the sternomastoid muscle. The incision should be made as near as possible on the same level as the centre of the swelling or a little below this point. The guiding landmarks in the operation are the transverse processes and the anterior surface of the vertebral bodies. Palpation can be made with one hand in the mouth and the other in the wound. Having located the abscess it should be opened after the manner of Hilton. [J. H. G.]

MEDICAL NEWS.

November 9, 1901. (Vol. LXXIX, No. 19).

1. Some Further Remarks on Hospital and Dispensary Abuses and Mismanagement, with an Account of the Means to be Employed to Mitigate or Arrest Them. THOMAS J. HILLIS.
2. The Relation of Sunshine to the Prevalence of Influenza. HOWARD S. ANDERS.
3. A Case of Suppurative Otitis Media Following Influenza; Operation without Opening of the Antrum; Complete Lack of All Constitutional Symptoms of Inflammatory Disease. O. WATERMAN.
4. A Case of Raynaud's Disease. W. A. HALEY.
5. Three Obstinate Cases of Empyema of the Maxillary Antrum, Cured with Injections of Solutions of Nargol. A. G. WIPPERN.
6. Treatment of Typhoid Fever. BASIL M. TAYLOR.

2.—H. S. Anders, in his article on the **Relation of Sunshine to the Prevalence of Influenza**, states the following conditions tend to increase the prevalence of influenza: (1) abnormal increase in the barometric pressure, and in

the absolute range between the highest and lowest pressures for the epidemic months; (2) sudden frequent and extreme alterations of abnormally high and low temperature ranges; (3) comparatively lower relative humidity during the prevalence of sharply epidemic influenza; (4) diminished precipitation, but short periods of unusual fog-giness alternating with periods of dryness; (5) marked prevalence of strong northerly winds frequently alternating with very calm weather; (6) predominance of relatively clear and sunny days during exacerbations of influenzal attack; these attacking periods having invariably been preceded by sudden thaws and relatively warm, damp, murky weather. [T. M. T.]

3.—O. Waterman reports a case with the following interesting points: (1) While the entire mastoid process had been destroyed during the rapid course of the disease, and while the insertion of the sternocleidomastoid muscle had been undermined, the bone surrounding the antrum and the antrum itself were found free from granulations and healthy; (2) Notwithstanding the severe destruction of tissue the patient was free from all those symptoms which accompany severe inflammatory conditions. [T. M. T.]

4.—W. A. Haley, after reporting a case of **Raynaud's Disease**, calls attention to the following points: That this disease is not confined to the young, nor is it devoid of fever, even before necrosis begins. Neither is it necessarily a benign disease. Either from the intensity of the pain, or from some other cause, there resulted at times an elevation of temperature which is thought not to be in Raynaud's disease. There seemed to be an effort on the part of nature to circumscribe the disease, as is noticed in erysipelas of the skin, not by a line of demarcation and a raised margin, but by a close blending of the normal with the pathological skin; but the process continued to involve new tissue. The macroscopical examination of the affected limb within an hour after amputation presented the following points of interest: the cut ends of the arteries and veins had lost but little blood; the skin maintained almost its original cyanotic appearance; the large vessels retaining their identity, while the smaller ones were lost in the tissues, which had every appearance of bruised tissue. Several clots of blood were removed from the long saphenous vein; one of the clots was some three or four inches in length and was removed by laying open the vein and lifting it out, it being well organized. [T. M. T.]

5.—A. G. Wipperfurth prefers **nargol**, a compound of silver, to silver nitrate for the reason that the nitrate coagulates the albumins of the tissues forming a protective covering over underlying structures. Its action is superficial in the treatment of purulent inflammations of mucous membranes. This is a peculiarly unfortunate circumstance, inasmuch as the germicidal and alterative effects of the drug are thereby limited to the surface of the membrane, while without penetration of the remedy into its structure the disease cannot be cured, although it may be held in abeyance for a period. [T. M. T.]

6.—B. M. Taylor, in the **Treatment of Typhoid Fever**, divides the disease into two classes: (1) Those who are healthy prior to the acute disease, and (2) those who have had some chronic disease for years. In the first class we have an opportunity to show our skill, or put the patient into the second class for the next case of fever. He lays great stress upon the proper food and the digestive tract, and says first remember the stomach and then the colon. [T. M. T.]

MEDICAL RECORD.

November 9, 1901.

1. Some Observations on the Symptomatology and Differential Diagnosis of Apoplexy; with Reports of Several Illustrative Cases.

THEODORE DILDER.

2. Some Remarks on the Etiology of Apoplexies.

W. K. WALKER.

3. Concerning the Clinical Significance of the Klebs-Loeffler Bacillus. ADOLPH RUPP.
4. A Case of Death from Ether Anesthesia, with Autopsy and Microscopic Study. HARLOW BROOKS.
5. Practical Results with One Thousand Cases of Nitrous Oxide and Ether Narcosis. H. W. CARTER.

1.—Diller believes that the occurrence of apoplexy, with the production of either paralysis or loss of consciousness, is far more common than a reading of the standard text books would lead one to believe. He referred to the case of a priest, aged 47 years, who suddenly became slightly clouded in his consciousness; but, recovering himself quickly, noticed that he was blind to the right. Ophthalmologic examination showed that the left halves of both retinæ were blind. He also referred to two cases of apoplexy of the central vessels of the retina and points out that such a condition is sometimes the forerunner of an apoplexy of a cerebral vessel. Apoplexy may manifest itself by a hemiplegia alone, without a loss of consciousness. He referred to a case of apoplexy producing loss of consciousness and prolonged mental disturbance, but not paralysis. He referred to a case of thrombosis with secondary softening, in which the diagnosis of brain tumor was made; to a case of cerebral softening in which the diagnosis of hysteria was made; and to a case of hemorrhage into the frontal lobe attended with violent and prolonged convulsive movements in which the diagnosis of hysteria was made. Apoplexy may be a symptom of paralytic dementia. He referred to a case of apoplexy in the pons and to one of apoplexy in the cerebellum. [J. M. S.]

2.—Walker discusses the etiology of apoplexy. Appreciation of the far-reaching and destructive influences of the various poisons upon blood-vessel walls, should lead to prompt, energetic and prolonged treatment of one known to have been subjected to their influence; and when family history reveals inherited instability or vulnerability of nervous tissue, early appreciation of the significance of the vague symptoms of disturbed circulation within the brain will enable us to do much to prevent the more serious developments and complications which we are so powerless to cure. [J. M. S.]

3.—Rupp concludes: (1) That clinically there are two kinds of diphtherias; those having the Klebs-Loeffler bacilli present and those having none. (2) That the character or quality of the Klebs-Loeffler bacilli that may be present in any case of diphtheria does not prognosticate its course or termination. (3) That Klebs-Loeffler bacillary diphtheria may be so mild as to simulate a simple tonsillitis, and yet the most virulent Klebs-Loeffler bacilli be present. (4) That virulent Klebs-Loeffler bacilli may be present in the throats of healthy people never doing any harm to the persons harboring them, nor harming in any noticeable way or manner those who have come into close and intimate contact with the bacilli-infected people. (5) That the Klebs-Loeffler bacilli are found associated with other bacteria in other diseases than diphtheria, but that they fail to exert any appreciable influence on the progress and decline of those diseases. (6) That the Klebs-Loeffler bacilli vary much in size and shape and the quality and quantity of their toxicity is not peculiar to any particular form. (7) That the virulence or disease-promoting qualities of Klebs-Loeffler bacilli can be determined only by experimental inoculation tests. (8) That the ubiquity of Klebs-Loeffler bacilli, and their irregular and varying forms, besides the inconsistency of their toxic qualities make it impossible to grant them any primary specific etiological importance in the pathogenesis of clinical diphtheria. (9) That the necessary influences and the favoring conditions, besides other factors of which we are still ignorant, enfold within themselves the secret of the real causes of clinical diphtherias. [J. M. S.]

4.—Brooks reports a case of death from ether anesthesia. The patient had a compound fracture of the forearm, which exposed the wrist and elbow joints, accompanied by rather extensive laceration of the muscles of that member. The autopsy showed interstitial myocarditis of moderate degree, complicating functional cardiac hypertrophy; chronic arteriosclerosis of marked degree in the aorta, but not extending to the smaller vessels,

excepting those of the heart; submeningeal edema of slight extent, limited to the cerebral vertex; pigmentation of the ganglion cells of the cerebral cortex and a similar condition of the cells along the floor of the fourth ventricle. [J. M. S.]

5.—The main advantages of nitrous oxide as a preliminary to ether are its almost perfect safety and its rapid and pleasant action; while the principal disadvantages of ether are its disagreeable pungent odor, its irritability to the respiratory mucous membrane, and the slowness of the onset of anesthesia. In using the two in combination or succession, the pleasant and rapid action of the gas supplants the prolonged disagreeable sensations of the first stage of ether inhalation. The number of patients who cannot take gas and ether Carter believes is exceedingly small. In neurotic patients, in children and in old people, the method is particularly valuable. In all pulmonary diseases, provided the heart is not affected, the use of chloroform is preferable to the administration of gas and ether. [J. M. S.]

THE NEW YORK MEDICAL JOURNAL.

1. The Treatment of Cutaneous Epitheliomata. CHARLES W. ALLEN.
2. The Future of Gynecology as a Special Branch of Surgery. ELY VAN DE WARKER.
3. The Lane Lectures on the Social Aspects of Dermatology. MALCOLM MORRIS.
4. Muscular Atony an Important Factor in Uterine Displacements. HENRY C. COXE.
5. Devitalized Air Toxemia, a Prime Cause of Tuberculosis. CHARLES DENNISON.
6. Curies of the Spine; an Analysis of a Thousand Cases. J. HILTON WATERMAN and CHARLES H. JAEGER.

1.—C. W. Allen concludes his article as follows: (1) Cutaneous cancer can be traced in almost all instances to preceding local irritation; (2) While other causes may be operative, it is not unreasonable to assume that infection may be one source of irritation occasioning cancer; (3) Benign epitheliomatous proliferations of infectious nature transmitted by contagion lend weight to this view; (4) Cancer is curable, but the disease may be allowed to progress until the patient no longer is; (5) No treatment short of the most radical measures should be tolerated; (6) In the application of caustic pastes and subsequent cauterizing dressings we possess a method not alone radical, but one which is in many conditions preferable to the knife; (7) The earlier treatment can be applied, the less likelihood is there of recurrence or of subsequent outbreaks in other parts due to cancerous tissue which has been left behind; (8) The X-ray as a means of treatment bids fair to prove quite as effective as caustic applications. [T. M. T.]

5.—C. Denison, in his article quotes the views of Dr. E. O. Shakespeare as follows: (1) It never has been, and never can be, shown that the *bacillus* is the "sole" cause of all the conditions classed as tuberculous, for other causes which produce susceptibility are entitled to quite as much consideration. (2) It is wholly presumptive to say because "the lungs are so generally involved" that the disease is almost exclusively transmissible through the expectoration. The function of the bronchial glands, the part played by the delicate unventilated lung tissues, and the retention of other poisons than the supposedly inhaled bacilli, all these facts need to be considered. (3) The statistics of Biggs and Johnson cited a large portion of humanity as having been at some time, or in some degree, infected with tuberculosis, and that, too, increasingly with the advanced age of the individual, an increase which, taken with the evidence of H. Schreiber, that new-born infants do not react to the tuberculin test, shows that the human race probably starts out free from the disease. This ought to prove, or at least to suggest, that there must have been a condition precedent to this disease acquired during life from peculiar environment. Such a fault of our civilization, if we can only find and acknowledge it, will explain the frequent occurrence of this disease. Then, to the reflective mind, this most fatal scourge of the human

race is as clearly due to non-conformity to healthful environment.

6.—J. H. Waterman and C. H. Jaeger, in their studies on *Carles of the Spine* have observed that the family history plays an important role in this condition. They found that over ten per cent. of the cases had tubercular parents. Another interesting observation was that the children of "Lungers" in Colorado were very rarely affected with tubercular diseases of bones and joints, and in the rare cases in which the children had hip or spine disease it ran a very mild course, hardly ever coming to the formation of abscesses and progressing favorably without any apparatus. They also found that children admitted to the wards of hospitals in a non-tubercular condition after leaving the hospital would develop hip or spine disease after some months. It was found that the disease varied in situation with the age of the patient. In the first five years of life it was found that every vertebra down to the sacral was affected with the exception of the first cervical. During the ages of ten to fifteen the highest vertebra found to be affected was the fourth cervical. After the fifteenth year the highest vertebra affected was the first dorsal and that only once. After the twentieth year the highest was the fourth dorsal and over thirty years the fifth dorsal. [T. M. T.]

2. The U. S. Army System of Personal Identification. C. H. ALDEN.
3. On the Establishment of Medico-Legal Diplomas, etc. WYATT JOHNSTON.
4. The Erickson Murder. F. H. BAKER.

1.—Many new and important problems confront the American medical profession in the Philippines. With the cessation of hostilities and the establishment of permanent garrisons, barracks and hospitals adapted to the tropics must be constructed to guard the whites from the dangers of living in their present make-shift quarters. Ice machines, water distilling plants and laundries must everywhere be installed. Measures for municipal sanitation must be enforced among the native population, to protect the white man from the effects of epidemics among his neighbors. General vaccination must be vigorously carried out, and lepers must be segregated and cared for. For the benefit of the natives, dispensaries and civil hospitals must be founded, where the indigent can receive scientific treatment and proper care free of charge. For the ultimate good of both the white and the brown inhabitants, as well as for the advancement of science, laboratories should be established for the investigation of the many unsolved problems of tropical medicine. The initiative and the execution in all these matters must depend upon the American army surgeon, unless a special medical service is established to look after the civil side of medical and sanitary administration. [J. M. S.]

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

November 9, 1901.

1. A Further Report of Permanent Catheterization. J. RILUS EASTMAN.
2. Fallacies in the Treatment of Urethral Diseases. ROBERT HOLMES GREENE.
3. New Method of Skiagraphic Diagnosis for Renal and Ureteral Surgery. G. KOLISCHER and L. E. SCHMIDT.
4. The Treatment of Pneumonia. DeLANCEY ROCHES, M.D.
5. Abortive Treatment of Pneumonia. W. L. DICKERSON.
6. Strabismus; Its Treatment. A. EDWARD DAVIS.
7. Typhoid Fever—Dietetic Treatment. LOUIS FISCHER.

1.—Eastman has employed Permanent Catheterization in 15 instances, the catheter remaining in place for more than 10 days in all, and for more than two months in two of the cases. The slight urethritis which was set up subsided

in a few days, the urethra developing a tolerance for the instrument. Catheters varying from 26 to 29 (Charrière scale) are chosen because they cause less irritation from friction than the smaller instruments and are not so apt to be dislodged. Cystitis was not produced by the catheter in any of the cases and in two in which inflammation of the bladder was the lesion for which the instrumentation was carried out, the pain and strangury were distinctly relieved. Among the reasons for draining the bladder by the permanent catheter are: the urine is removed by the natural exit; if there be a perineal defect it closes more quickly because unirritated by the flow of urine; the calibre of the urethra is maintained; the difficult and often dangerous efforts to introduce a catheter after operations on the urethra is avoided; the urine may be drained into a receptacle; the danger of urinary absorption and the danger of bacterial infection are reduced, since the area of unprotected tissue with which the urine comes in contact is diminished; pain and fever are slight; narrowings of the urethra may be removed by pressure absorption, and the procedure may be utilized for cystitis without subjecting the patient to the danger of a surgical operation. [F. T. S.]

2.—Green comments on the slight amount of real progress that has been made in the treatment of diseases of the urethra. Excluding the traumatic cases it is said that strictures requiring incision are almost never met with, certainly not in men under 40 years of age. The irrigation method for the treatment of acute urethritis makes the patient more comfortable and quickly changes the discharge into a muco-purulent exudate, but it drives the germs to the deeper layers of the urethra, increases the danger of latent urethritis, and augments the prostatic infiltration. The best treatment is to refrain from local measures for the first 6 or 8 weeks. The writer believes that gentle prostatic hypertrophy is an inflammatory enlargement and most frequently due to urethritis. He is supported in this belief by Harlow Brookes who studied 30 enlarged prostates microscopically. [F. T. S.]

3.—The authors introduce into the ureters a wire which is made of lead blended with antimony, and then skiagraph the kidneys and ureters. The course of the ureters may be determined; the location of the renal pelvis; the situation of calculi, etc. [F. T. S.]

4.—Rochester gives an account of "the treatment of pneumonia." In his article he gives a brief view of the clinical course of this disease; the chief cause of death, and includes a table which deals with a number of cases of pneumonia treated by himself and Dr. Charles G. Stockton, of Buffalo. In this series 168 cases were treated with 17 deaths—a mortality of 10.12%. In this group of cases are included individuals from all walks of life and of all ages, covering a period of a little over ten years. The following are his conclusions which we quote in substance: "1. The sustaining of the metabolic process of the individual by the administration of easily digested or predigested foods in small quantities at stated intervals, the administration of large amounts of pure water for eliminative purposes and the administration of oxygen gas by inhalation whenever the absorbing surface of the pulmonary mucosa is involved to such extent as to interfere with proper metabolic oxygenation. 2. Elimination, (a) by the liver and bowel through the vigorous use of calomel and salts; (b) by the skin through sweats by external heat; (c) through withdrawal of blood when indicated by right heart distension. 3. Stimulation of heart by strychnin, alcohol or ammonium carbonate, and in suitable cases by subcutaneous injection of normal salt solution. 4. The local treatment of the lung by leeching, wet cupping or dry cupping as indicated." [F. J. K.]

5.—Dickerson makes a plea for the use of cardiac depressants in the treatment of the congestive stage of pneumonia. The author admits that as a rule cardiac depressants are used too late, but when given during the con-

gestive stage these drugs are of value. He recommends veratrum viride, believing that it is safer than other cardiac depressants and that it is as efficient as it is safe. He advises the administration of the tincture (U. S. P.) in oft-repeated doses until the physiological effect is noticed, namely, some nausea, relaxation of the skin, and a reduction of the pulse rate and temperature. He advises not stopping its administration as soon as the exudate is formed, but to continue its use so long as the pulse is angry and the blood pressure too high. He emphasizes that the administration of this drug lessens the amount of exudate and seems to cut short the attack. [F. J. K.]

6.—See Phila. Medical Journal, June 15, 1901, page 1139.

7.—Fisher discusses a dietetic treatment of typhoid fever. This author writes that the successful management of a typhoid fever case does not depend on the administration of drugs excepting eliminatives, but depends solely on supporting the vitality by giving liquid foods of a nutritious character which are enumerated in his article. These may be given either by the mouth, rectum, or subcutaneously. (In the form of the white of an egg added to normal salt solution). He believes that acidulated drinks are not only grateful to the feverish patient but appear to inhibit bacterial action. [F. J. K.]

AMERICAN MEDICINE.

November 9, 1901.

1. Trional Fatalities. ARCHIBALD CHURCH.
2. Diagnosis and Treatment of Round Ulcer of the Stomach. N. S. DAVIS.
3. The Nature of Internal Lesions in Death from Superficial Burns. JOHN McCRAE.
4. The Bacteriology of Otitis Media, etc. JOHN FUNK.
5. A Case of Elephantiasis. JOHN M. BERTOLET.
6. Appendix Vermiformis Passed in Stool.

W. L. WALLACE.

1.—Church reports the case of a man, aged 40 years, who sprang from a family of decided neurotic tendency. In childhood the patient was of pronounced nervous temperament. In 1899, he suffered from nervous dyspepsia, insomnia, loss of weight and neurasthenia. In 1900, he had an attack of diphtheria. In September, 1900, he suffered from insomnia for which he took trional in 5-grain doses every hour for 8 hours for 3 days. Two months later he began to use trional as before. Later he began to take the drug upon his own motion and used from 10 to 20 or 30 grains a night. This drug he used almost continuously up to a short time before his death in March, 1901. It was found that the patient's urine was dark red in color for weeks. There was trace of albumin, a distinct trace of hematoporphyrin by the spectroscope and a few hyaline casts. At the autopsy the right kidney showed several small areas of interstitial degeneration. The withdrawal of the drug was followed by the disappearance of the hematoporphyrin within 48 hours. The author points out that abdominal distress and urinary derangements, including hematoporphyrinuria, indicate trional poisoning of a very grave character, and that in so-called safe doses, trional may give rise to serious even fatal toxic conditions. [J. M. S.]

2.—Davis says that in round ulcer of the stomach a reduced acidity of the urine and a well-marked alkaline wave after meal is found. The production of a large amount of acid by the glands of the stomach increases the alkalinity of the blood, and therefore reduces the acidity of the urine and often makes it alkaline. The amount of chlorids in the urine will be reduced especially during periods of digestion. [J. M. S.]

3.—From a study of fatal cases of superficial burns, McCrae concludes: (1) That the entire pathologic picture presents great similarity to the conditions found in the diseases characterized by the presence of toxins of bacterial origin in the blood. (2) That damage to the lymphatic tissue is a constant feature, but is not necessarily

focal, some cases presenting only diffuse degeneration. The patients who live but a few hours after infliction seem more likely to present a focal condition than those who live a longer time, as the condition which the author interprets as proliferation and phagocytosis is one that may rapidly disappear. (3) That the focal lesions are not a true necrosis, but rather a proliferation of the endothelial cells of the reticulum and the capillaries, and a phagocytosis by the leukocytes and endothelial cells, to which latter is due the fragmented, disintegrated appearance that suggests a true necrosis. [J. M. S.]

4.—Will be abstracted when finished.

5.—Bertolet reports the case of a woman, aged 50 years, who had a family history of tuberculosis. In the year 1878 she fell and injured her left knee-cap. Two months after the injury had, to all appearances, completely healed, her leg began to swell and rheumatic pains appeared. A diagnosis of elephantiasis was made after finding live filaria sanguinis in the blood at midnight. The necropsy showed that the lymphatics were clogged and dilated enormously and that gangrene had attacked the right foot. The author believes that the filaria were in the system from the large amount of fruit that the patient had eaten. [J. M. S.]

6.—Wallace reports a case of appendix vermiformis passed in stool. [J. M. S.]

5. I. On the Diagnosis of Diphtheria. II. A Double Stain for the Bacillus Diphtherie.
ROBERT L. PITFIELD.

1.—This noteworthy article was read before the British Congress on Tuberculosis, and was abstracted in this journal upon its appearance in the *British Medical Journal*. [T. L. C.]

2.—De Forest Willard reports a case of aneurysm of traumatic origin of the thoracic aorta, which was treated by the introduction of wire and electricity. The position of the tumor and the absence of pulsation in the neck, and the character of the chest sounds, indicated a traumatic lesion of the descending thoracic aorta rather than of the arch or of ascending portion, unless the dilatation was at the very origin of the vessel. As the conditions were growing worse, and rupture certainly approaching, the patient consented to accept the risks of the only operation that offered any chance of success, the introduction into the sac of a certain quantity of wire as a framework or skeleton, each coil of which might form a nucleus for coagulation, producing eddies in the sac and final consolidation. To facilitate coagulation upon and around this wire framework, the coagulating power of galvanism was brought to bear. In this operation of wiring it is essential that strict asepsis be secured, and that no elements of suppurative be introduced, since sepsis and faulty technique are the most frequent causes of death. After six or eight feet of wire had been inserted, the wire was connected with the copper conducting cord of the positive pole of a galvanic battery. The negative pole was attached to a large, flat electrode sponge-covered pad, placed between the scapulae. Five milliamperes were turned on at first, and the force of the current was increased by fives, the patient perceiving plainly each addition, and complaining of pain chiefly in the back, especially when new pieces of wire were connected. More wire was threaded in through the cannula until about twenty feet of coils were inserted. Nine weeks after the operation the man was so well, that he could not be restrained, and he left the hospital in spite of protest. Good consolidation of the anterior portion of the sac at the seat

of operation was positive. Willard makes some remarks upon the applicability of this method of treatment and its technique in aneurysm of aorta, and also gives a résumé of the literature on the subject. He thinks that ten cases have been positively benefited; one is uncertain, and while the remainder died at various periods within one year yet nearly all of those, that survived the immediate effects of the operation, were rendered decidedly uncomfortable. [T. L. C.]

3.—J. F. Schamberg and J. Frank Wallis describe **wax models and their preparation and uses**. These models have manifold advantages over pictorial representations in the flat. They serve admirably in the portrayal of cases to illustrate didactic lectures. The method of preparing these models is furnished. [T. L. C.]

4.—Charles H. Frazier discusses the method of instruction supplementary to the clinic, the ward-class and the didactic method, and gives the method of teaching as is followed in his department in the University of Pennsylvania, the case method of teaching. He believes the method encourages the student to think for himself, and develops his powers of reasoning and his ability to discriminate between the important and unimportant facts as presented in the history of a given case. It encourages the student to read more widely, to consult many authorities, and thereby broadens his scope of knowledge. The clinical histories are presented to the student as they will be when he engages in actual practice. The method possesses certain features which appeal to the earnest student, and arouses in him no little enthusiasm in the pursuance of this branch of work. In conclusion he publishes three papers prepared by a member of the third-year class, as illustrating the way in which the cases are treated. [T. L. C.]

5.—Robert L. Pitfield discusses the **diagnosis of diphtheria**, and believes that Klebs-Löffler's serum culture method is by all means the best method of positively diagnosing diphtheria. A description of the diphtheritic membrane is given. He describes the practical method in which Löffler's alkaline blue is used to stain the slide after heating, and mentions the importance of the presence of little black or bluish-black points situated at one or both poles of the bacillus, with occasionally a little point in the middle. If these point-bearing bacilli are found in the fibrin, one can be very certain that the case is diphtheria. There are many other organisms found in the diphtheritic membrane by this method, but if they contain **chromatin granules** and are curved and irregular in outline, they are diphtheria bacilli. If the case is tonsillitis, by the same method, single round coccil or strepto- or diplo-cocci are to be found, but no chromatin point-bearing little rods will be seen. Pitfield also recommends a double stain for the bacillus diphtheria. He uses three simple solutions. A.—Silver nitrate, gram 5; Aqua destill., c.c. 5; sat. sol. (alcoholic) fuchsin, c.c. 3. B.—Pyrogallie acid, gram 1; 10 per cent. sodium hydrate in water, c.c. 5; aqua destill., c.c. 10. C.—Carbol fuchsin solution, drops 10; aqua destill., c.c. 10. After making a smear on a slide or cover, carefully fix with heat, pour on solution "A," boil a minute, wait a minute, and then wash. Then pour on solution "B" and do the same; then wash and pour on "C" for a minute or two, wash, dry and examine. The organisms will appear delicately pink, of slightly uneven shades, corresponding to the heaping of the protoplasm. At one or both ends, and after in the middle, brilliantly shining black points appear, which stand out exceedingly sharp and clear. This makes a novel field of pink and black. The cell membrane appears a gray-brown of very light shade in this preparation. [T. L. C.]

VRATCH.

July 21, 1901.

1. The New Method of Medico-legal Detection of Human Blood and That of Animals, and a Few Remarks Concerning It. M. A. SCHIROKICH.
 2. On the Question of Abdominal Adhesions.
E. Ia. KATUNSKI.
 3. A Few Cases of Serious Injuries to the Head in Children. L. M. KONTOVT.
 4. Transplantation of the Ovaries. A Few Experiments on Animals. V. I. LUKASHEVITCH.
- 1.—Schirokich furnished experimental proof of the **absolute value of the method of detecting human blood**, proposed

recently by Ehrenhut and subsequently studied by Wassermann and Schütze. He immunized a rabbit by injecting various quantities of blood obtained at the Maternity Hospital from the human placenta and cord. The injections were not made at regular intervals, as prescribed by Wassermann, owing to the irregularity of the supply. At the end of 2 months the rabbit was bled from the left jugular vein and 25 c.c. of blood, or 15 c.c. of serum, obtained. Two to three drops of this serum were added to salt solutions (1.6%) of the following blood stains: (1) Blood from a new-born, on filter paper, 2 weeks old; (2) blood from an adult, on ordinary paper, 1½ weeks old; (3) the same on gauze, 2 years old; (4) blood from a horse; (5) blood from a ram; (6) blood from a bull, the last three stains were on paper, 5 days old; (7) blood from a cadaver of an adult who died of CO poisoning, on a rag, 1 year old; (8) blood from a goat, on wood, 2½ years old; (9) blood from a camel, on a rag, 2 years old; (10) blood from a guinea pig, on filter paper, 2 years old; (11) blood from a cat, on filter paper, 1 year old; (12) blood from a rabbit, on a rag, 1 year old; (13) blood from a hog, on a rag, 2½ years old. The clear solutions of Nos. 1, 2, 3 and 7 became **opalescent in about 2 minutes**; within ¼ of a hour **distinct flocculi formed** and within 1 hour a marked sediment. All other solutions remained clear during that time, but in 4 to 5 hours developed an opalescence which resulted in a sediment within 24 hours. This behavior of blood other than human is not mentioned by other observers, and while it has no practical significance from a medico-legal standpoint, it is nevertheless well to bear it in mind. **Only the changes taking place during the first hour should be taken into account.** In view of the difficulty of immunizing an animal, the author suggests that the blood once obtained should be preserved in sterile capillary tubes, or what is more practical, on filter paper. Satisfactory results were obtained with the blood dried on filter paper and kept for 1 month. [A. R.]

2.—Katunski claims that clinicians and authors of textbooks pay but little attention to **abdominal and peritoneal adhesions**, following injuries or operations. Even slight adhesions, involving important structures, may bring about a train of severe symptoms, constituting a disease which is often difficult to diagnose. His personal observations as well as the data obtained from the literature on the subject lead him to the following conclusions: (1) Peritoneal adhesions in general, and typical peritoneal adhesions, first described by Gersuny, have an important bearing on the study of diseases of the peritoneum and the abdominal viscera, including the internal generative organs of the female. (2) The subject of typical peritoneal adhesions is greatly in need of a thorough clinical investigation to clear up the cause, study the clinical picture, determine the objective signs and, finally, solve the question of treatment. (3) The great importance of typical adhesions makes it indispensable for the surgeon to establish their presence or absence in every laparotomy. (4) In view of the topographo-anatomical peculiarities of typical peritoneal adhesions and their correlation to other diseases of abdominal and female generative organs, only such operative procedures should be undertaken which would make it possible to remove the adhesions if present; otherwise the surgical intervention for the removal of symptoms will prove a failure. (5) Among the contraindications to the vaginal route for entering the abdominal cavity should be included also the presence, evident or suspected, of peritoneal adhesions. [A. R.]

3.—Kontovt reports 9 cases of **serious injuries to the head in children** from 1½ to 13 years of age. In 7 the injury was caused by a kick from a horse. The skull was fractured in all; in some the brain was seriously involved. All made a good recovery. Of the 4 children whose subsequent history could be traced, 2 showed the after-effects of the injuries. In one the development was retarded, while in the other the memory was affected. These cases demonstrate the fact that the skull of the young, owing to the osseous construction, suffers less from traumatism than that of the adult. [A. R.]

4.—Lukashevitch has done some experimental work on **transplantation of the ovaries**. The animals used were rabbits, guinea pigs, dogs and cats. The ovaries of a given animal having been removed, fresh ovaries from another were substituted, being attached by the mesovarium and left free in the abdominal cavity. The results of these experiments lead the author to the following conclusions:

(1) Ovaries on one animal may be transplanted into another, irrespective as to whether the animal is herbivorous or carnivorous. (2) The transplanted ovaries take root, are nourished and partially perform their function. (3) For a successful transplantation it is necessary: (a) an aseptic operation; (b) careful stitching of the mesovarium of the transplanted ovary, the lower half of the latter being enveloped in a fold of peritoneum so as to increase the nutrition and imitate nature; (c) two ovaries should be transplanted so as to have more ovarian tissue; (d) the ovaries should be attached at the site of the original ovaries, in the broad ligament; (e) pressure from neighboring organs on the ovaries should be avoided, also the passage of sutures through the ovarian tissues. (4) The transplanted ovaries, as a rule, do not live very long and soon begin to show retrogressive changes, such as senile atrophy characterized by vacuolization, loss of follicles and ova, thickening of the parenchyma, narrowing of the lumen of the blood vessels and thickening of their walls and at times also calcareous degeneration. (5) Such short duration of the life of the ovaries is explained mainly by the lack of nutrition, owing to the small size of the new-formed blood vessels. (6) Nevertheless, some of the transplanted ovaries, the larger and more successfully grafted ones, may live for a considerable time (3 years in the author's experiments), partially functioning and preventing atrophy of the generative organs and obesity and also improving the general condition of the patient. (7) In no case did pregnancy follow the transplantation of the ovaries, although the animals were kept together with the males. [A. R.]

ARCHIVE FUER EXPERIMENTELLE PATHOLOGIE

(Band 46, Hefte 1 and 2.)

1. Investigations Concerning the Distension of Intravenously Injected Na Cl and Na² SO⁴ Solutions. SOLLMANN.
2. The Chemical Nature of Ricin. JACOBY.
3. A Clinical and Experimental Contribution to the Diagnosis of Renal Diseases. WALDVOGEL.
4. Acetonglycosuria. MUELLELT.
5. Some Morphine Derivatives Which Produce Convulsions and Their Point of Action. BARNES.
6. The Determination of the Blood Pressure in Human Subjects. v. RECKLINGHAUSEN.
7. Compounds of Glycosuric Acid with Substances of a Fatty Series. NEUHAEUER.
8. The Fate of Atropin and Cocain in the Animal Organism. WIECHOUWSKI.

1.—Aquimolecular solutions of Na Cl and Na² SO⁴ when brought directly into the blood stream in large quantities disappear very rapidly from the blood stream; even during the injection (lasting 3 minutes) the greater portion of these salts had disappeared, and in a half hour the constitution of the blood is about as it was originally. The total quantity of blood is diminished in spite of the injection of a large quantity of fluid. The fluid and salts leave the blood stream first to enter the "tissues" and then pass out in the urine; the tissues may pass off what has entered them even before the blood has become normal again. At times large quantities of the substances injected are excreted through the intestine. The wandering of the fluid and salts up to their ultimate excretion is completed in about half an hour; the salts are excreted more rapidly than the fluid and Na Cl more rapidly than Na² SO⁴. The excretions is first very rapid, soon reaches its maximum and then falls, but remains increased throughout the experiment. The increase in the amount of blood at the immediate time of injection varies, but may be very marked. The molecular concentration of the serum, strange to say, shows no marked changes; there is slight increase in molecular concentration directly after the injection, but even this soon disappears, and the concentration may decrease if the injected salts leave the vessels very rapidly. The urine shows a molecular concentration

(in inorganic salts) shallar to that of the blood, these salts being chiefly those injected, though Na Cl carries other salts with it in greater concentration than they are found in the serum. After injecting Na² SO⁴ the urine on the contrary becomes nearly chloride-free. The concentration of the urine in inorganic molecules was inconstant but was in the beginning universally proportionate to the diuresis. It appeared probable that the plethora produced by the injection caused increased pressure in the capillaries and consequently the increased filtration processes, first toward the tissues. The urine excreted through the glomeruli is free from organic substances and hypotonic. Through osmosis the urine increases the salts which it contains until the concentration equals that of the serum, but chlorides for some reason are never coined out of the organism in quantities possessing a certain definite amount. Sollmann's work convinces him that the organic constituents of the urine are passed into the urine through a definite secretory power of the epithelium of the tubules. The total concentration of the urine is greater than that of the blood serum and the explanations offered for this are, (1) that everything passe by filtration and the concentration is afterwards raised by absorption of water; (2) that the water and inorganic salts passed by filtration and osmosis and the organic constituents reached the urine by means of a "vital" secretory act of the tubules. Sollmann adheres to the latter view chiefly because the concentration and the diuresis bear an inverse ratio to each other directly after the injection and afterwards ran parallel with the concentration maintaining a constantly and somewhat higher relative level. This can be readily explained only by considering the diuresis at the beginning as due to increased pressure, while later the excretion depends more upon secretory action and consequently the concentration becomes relatively high. The methods used in the investigation were in brief, injection of solutions of Na Cl or Na² SO⁴ in quantities equal from 63% to 521½ of the reckoned amount of blood, and making preliminary and subsequent determinations of the freezing-point of the blood serum and urine, reckoning the organic substances, the non-chlorides and the chloride substances of the urine. The latter method was thought more reliable for this study than comparing the electric conductivity of two fluids so different as are the blood and urine. [D. L. E.]

2.—Ricin was purified by repeated precipitation with ammonium sulphate and dialysis. It retained its poisonous properties and its agglutinating action upon red blood cells, though it no longer gave reactions for albumins. Hence these actions are due to some substances in the ricin which is not an albumin. The pure ricin can be preserved for several weeks at any rate. It was readily destroyed by trypsin and hydrogen peroxid while when in solution with albumins it is resistant to trypsin and but little affected by hydrogen peroxid. [D. L. E.]

3.—Waldvogel presents a series of studies of the freezing point of the urine and its relation to the total amount of urine to the Na Cl and to the total nitrogen. He bases his conclusions upon cases of nephritis, cases in which one kidney was practically destroyed by disease such as pyonephrosis, and in several of which the damaged kidney was removed and the urine studied after the operation as well, and also upon observations of persons in health and with various diseases other than nephritis, and upon experiments (nephrectomy, double and single) in animals. He decides that values obtained for the freezing-point, the freezing-point multiplied by the daily amount of urine, the freezing-point divided by the total amount of Na Cl or by the total nitrogen, are all variable and are not typical either even in inanition or after extirpation of a kidney. So far as the condition produced by double nephrectomy in animals is analogous with uremia in man, one may say that blood letting and saline or water injections do not decrease the concentration of the blood in uremia as indicated by the freezing-point. If one kidney is known to be

destroyed (as by pyonephrosis) and the product of freezing-point by total urine is still above one degree the prognosis as to the functioning power of the other kidney is good. If within a few days after a kidney extirpation the same value is found below one degree one may say that the remaining kidney is unequal to its task. His investigations did not support the view that there is an osmotic exchange of chloride containing and chloride-free molecules in the urinary tubules. [D. L. E.]

4.—As a result of animal experiments Müller believes that the glycosuria that follows acetone-poisoning is a result of the narcosis produced, and is immediately due to the reduction of bodily temperature or to the severe dyspnea. The fact that the bodily temperature is not always depressed or that there is not always dyspnea explains the relatively infrequent observation of glycosuria with acetone poisoning. It also explains the fact that other substances of the alcohol or chloroform groups in rare cases produce glycosuria, and it particularly explains the glycosuria sometimes seen after ether narcosis—i. e., it is not a direct result of the ether, but of secondary disturbances in the organism set up by the ether. Because of the abnormal reaction to Trommer's test in a number of instances Müller believes that paired glycosuric acids were present in considerable amounts in these cases of poisoning. [D. L. E.]

5.—Barnes finds that while morphoxyacetate and its homologues are relatively not poisonous, their methyl and ethyl ethers are active convulsive poisons which, in frogs and mammals, act similarly to picrotoxin. While in the frog the spinal cord is involved in the poisoning, in rabbits the only seat of poisoning is in the pons and the spinal cord. Medulla, cerebellum and cerebrum are unaffected. [D. L. E.]

6.—v. Recklinghausen describes a new instrument which he has devised for measuring the arterial pressure in clinical and experimental work when a vessel can not be opened. It consists of a broad cuff-like band of rubber which can be inflated by means of a pump which is attached by tubing. There is a metal plate over the outer side of the cuff and hence the inflation must take place inwardly. If then the cuff be placed on a limb (best the arm) and inflated, it gradually compresses the tissues until a pulse can no longer be felt below. In this way or by means of a series of tracings, one can learn the manometer reading at the time when the pressure from without overcomes the arterial pressure. Recklinghausen gives a long study of the factors influencing blood pressure and thereby influencing the accuracy of instruments used to determine the degree of blood pressure. Gärtner's instrument, he thinks, suffers from the fact that the finger ring is too narrow and often does not fit well. He has constructed a special ring, much broader and made to fit the basal phalanx, with which he states that he got much more constant and more reliable results than with the usual ring. The results from his own instrument seem to have been very satisfactory. The chief point of excellence of the instrument is that the cuff is broad and therefore a large portion of the artery is compressed at one time, thus avoiding the error attendant upon compression at one point, and secondly, the tissues of the whole circumference of the arm are compressed at one time—i. e., the compression does not act from one side alone and against varying thicknesses of tissue and different degrees of rigidity in different persons. [D. L. E.]

7.—A chance observation that the administration of fermentation amyl alcohol led to the appearance of paired glycuronic acid in the urine induced Neubauer to investigate the effect of aliphatic alcohols. Ketones and aldehydes and various other substances, practically all alcohols and ketones, various unsaturated carbohydrates and numerous aldehydes were excreted in part at least paired with glycuronic acids. This was the case with substances of the fatty series as well as with cyclic compounds, though methyl alcohol, the higher primary alcohols, and the polyatomic alcohols of the fatty series were exceptions, as were

some of the primary aromatic alcohols. Since the normal urine contains but very small amounts of paired glycuronic acid one is justified in believing that the substances investigated do not occur in any considerable amount as intermediary products of normal metabolism. [D. L. E.]

8.—Both cocaine and atropine are largely decomposed in the animal organism, cocaine much more markedly than atropine. About 5% of cocaine and about 33% of atropine pass the kidneys unchanged. Rabbits decompose cocaine completely. Egonine and tropin were looked for as decomposition products of atropine and cocaine, but could not be found in recognizable amounts. [D. L. E.]

BERLINER KLINISCHE WOCHENSCHRIFT.

July 22, 1901. (No. 29.)

1. Concerning the Development and Perforation of the After-Coming Head. W. NAGEL.
2. Contribution to the Study of Tabes in Women. P. FEHRE.
3. Concerning Some Observations of Pest in Bombay During the Present Year. M. HAHN.
4. The Changes of the Polynuclear Leukocytes in Some Infectious Diseases. H. HIRSCHFELD.

1.—Nagel's case was that of a primipara who had menstruated last on July 7th, 1901, and in whom the membranes had ruptured on April 13th, at 8 o'clock in the morning, one hour after the onset of labor pains. The patient presented various signs of rachitis and gave a history of having learned to walk only at her third year. Pelvimetry showed the following: Distance between the spines of the ilia was 26.5 cm.; between the crests of the ilia 27 cm.; external conjugate 15 cm. Upon measurement the author found the internal conjugate 8 cm., leaving a true conjugate of 6 cm. The position of the child was that of the first position, vertex presentation and from the os uteri there projected the left arm of the child and a loop of prolapsed cord which upon the arrival of the author no longer pulsated; the head had not yet entered the pelvis. The perforation of the head therefore seemed particularly difficult. As the child was not alive, Cæsarian section was not advised. The author succeeded in lifting up the child toward the anterior portion of the mother's body and perforated the posterior portion of the head. He advises this procedure in all similar cases and discusses in detail allied manipulations. [M. R. D.]

2.—Will be abstracted when completed.

4.—The author observed the changes in the polynuclear leukocyte granules in certain infectious diseases as well as the change of the tinctorial properties of the granules. He observed that they stained deeply with methylene blue in contradistinction to the normal condition. These changes were observed to be almost constant in pneumonia, measles with bronchitis, scarlet fever and in phthisis associated with high fever. The changes generally occurred at the height of the fever. Furthermore it was observed by the author that in staining with methylene blue and with methylene blue with eosin, that there were seen in the protoplasm of the polynuclear leukocytes, situated principally at the border of the cell, but also present in its centre, one or more spherical or elliptical bodies whose nature and significance have not yet become established. By triacid staining these bodies cannot be demonstrated. The question arises whether these products represent degeneration of the protoplasm or a nuclear degeneration, or, whether they are centrosomes. [M. R. D.]

July 29, 1901. (No. 30.)

1. The Question of the Heredity in Pathology. F. MARTIUS.
2. Poisoning with Carbon Bisulphide. E. MENDEL.
3. Concerning Chronic Pentosuria. F. MEYER.
4. The Frequency of Herpes Zoster. E. HOENNICKE.
5. Contributions to the Study of Tabes in Women. P. FEHRE.

1.—Will be abstracted when completed.

2.—Mendel's observations of carbon bisulphide poisoning

embrace the cases of two workmen who had been employed as vulcanizers. The following changes were noticed in consequence of the poisoning. Degenerative atrophy of the interosseous muscles in both hands and feet, and particularly in the thumbs and little fingers; weakness in the arms and legs. Anatomically the author considers the clinical picture as a poliomyelitis, which is also substantiated by other authors. Out of nine workmen in the factory the majority were affected. Experimental investigation has shown that carbon bisulphide affects various portions of the nervous system, both centrally as well as peripherally, and therefore the author believes that the lesion is not confined to one nerve area, but that it is considerably distributed. [M. R. D.]

3.—The author reports the fifth case of pure **pentosuria**, affecting a man 39 years of age, neurasthenic, markedly emaciated, with a pronounced tolerance for carbohydrates, and in whom the pentosuria was unaffected in spite of the liberal ingestion of carbohydrates. The diagnosis was made according to the so-called orcin test. In the author's case the diagnosis of **diabetes mellitus** had been made and the patient treated for it. The patient was subsequently pronounced cured in consequence of a polarization test which proved negative. The pentosuria in this case was reduced to one-half, not by either a rigid or an unrestricted diet, but by a mixed one, consisting of the ingestion of milk and definite quantities of carbohydrates. [M. R. D.]

4.—The author's observation, which embraces 164 cases of **herpes zoster** treated in ten years at Max Josef's Polyclinic in Berlin, comes to the conclusion that herpes zoster represents about 1% of all diseases of the skin. It affects both sexes equally, but shows itself particularly during youth, and that between the ages of 15 and 30; it rarely occurs in very young or old individuals. With one exception the eruption affects those regions which have the most nerve distributions, and that is the area of the trigeminus. Both sides of the body are equally affected, although bilateral zoster is rare. Epidemics occur in the spring and fall, although sporadic cases occur throughout the year. Physicians and nurses seem to suffer particularly during epidemics, but no other vocation seems to be predisposed. [M. R. D.]

5.—The author has analysed the etiological relations of **tabes**, in 47 cases affecting women. He arrives at the following conclusions: As a rule the same etiological factors found in men also apply to women. Syphilis by all means plays an eminent role in the etiology of tabes in women. The puerperal state may intensify the disease in tabetic women. The author calls attention to the facts that the increased association of women with various vocations previously held by men and the increased dissemination of syphilis appear to materially, both relatively and absolutely, increase tabes in women. [M. R. D.]

August 5, 1901. (No. 31.)

1. Puerperal Psychoses. E. MEYER.
2. Enuresis in Childhood. M. THEMICH.
3. The Priority of Cesarean Section per Vaginum.

A. DUEHRSEN.

1. The Problem of Heredity in Pathology. F. MARTIUS.
5. Human and Bovine Tuberculosis. R. VIRCHOW.

1.—Meyer observed at the psychiatric clinic at Tübingen that among 1101 insane women there occurred during six and a quarter years 51 puerperal psychoses, or 4½%. Those occurring during pregnancy were not included, but only those occurring during the puerperium and lactation. There were 11 cases of melancholia, four periodic melancholia, three circular psychoses, five paranoia, nine acute dementia, 11 katatonia, two hebephrenia, two epilepsy and one hysteria. An isolated, pure mania was not observed. The author states that there is no specific puerperal psychosis and that none of the phases represented in these conditions differ from those dependent upon the generally recognized etiology. In five cases puerperal infection and mastitis were present, and in 29 cases family history of psychoses. [M. R. D.]

2.—The author is opposed to the views that enuresis is due to muscular weakness or to local cause at all. He considers it purely as an hysterical phenomenon. Most of the children suffering from enuresis manifest a neuro-pathic family history, and not rarely other hysterical stigmata are also present. Another proof of the hysterical na-

ture of the infection is the frequent occurrence of epidemics. The best treatment is change of surroundings, isolation of the patient, faradization and the observance of hygienic principles. Other successful measures are to be attributed to suggestion. [M. R. D.]

5.—Treated editorially in *Philadelphia Medical Journal* of August 24, 1901.

August 12, 1901. (No. 32.)

1. The Employment of Subcutaneous Injections of Gelatine for Hemostasis. GRUNOW.
2. The Associated Movements of the Musculature of the Lids and Nose. BERNHARDT.
3. Cataract Operations in the Aged. MENDEL.
4. Pathogenesis of Delirium Tremens. BONHOEFFER.
5. Changes in the Central Nervous System following Ligation of the Thyroid Vessels. O. MAAS.

1.—The author reports the results obtained in 27 cases. The solution employed consisted of 2g. of gelatin to two parts of normal salt solution, the dose employed being 200g. daily, injected beneath the skin of the thigh. Grunow suggests that in addition to this method, the other hemostatics be also employed. He furthermore urges the continuance of the procedure for some time. Fever was observed in all the cases, but never any serious complications or results. If any advantage is derived, it is to be ascribed to the increase of the coagulability of the blood, caused by gelatin. The author's observations are as follows: 1. He has observed the efficacy of the procedure in hemorrhages affecting internal organs. The mild disturbances accompanying the subcutaneous injections of gelatine do not contraindicate them. 3. He urges the protracted employment of the method in all internal hemorrhages. 4. Often the procedure must be reinforced with other hemostatics. [M. R. D.]

2.—The following phenomenon was observed by the author in otherwise normal individuals: on closing the lids, and especially lightly, there is a synchronous dilatation of the nasal alae. He found it present in 15% of the examined cases. According to the author the phenomenon is to be attributed to anomalous anatomical development of the involved structures. [M. R. D.]

3.—In spite of the facts, that reclamation of the lens in the very aged at one time was largely employed, and is still to some extent, the author concludes from his observations at Hirschberg's clinic, that extraction is after all the most feasible procedure, even very late in life. His observations embrace 1645 cases of nuclear cataract, among which there were 36 patients over 80 years of age. Only in two cases were the results not entirely satisfactory. Advanced age does therefore not offer an unfavorable prognosis for cataract extraction. In very restless patients, general anesthesia may be employed. Delirium will occasionally occur, but the most serious complications are those related to the heart, lungs and bladder. In one case heart disease gave rise to pulmonary edema, which, however, was controlled by morphine. [M. R. D.]

5.—The experiments were performed on dogs. In all the examined cases degeneration was present in the spinal cord. In the brain degeneration was present, extending to the postero-lateral and pyramidal tracts. The longer the animals were kept alive after the operation, the more marked were the changes. [M. R. D.]

1. Leyden observed some years ago peculiar bodies in the fluid removed from the peritoneal cavity of a patient who was at that time thought to have carcinoma. The autopsy ultimately confirmed the diagnosis. The same bodies were afterward found in the fluid from cases of carcinoma of the pleura, from fluid obtained by direct aspiration of a malignant growth, and they were also found in smear preparations from the cut surfaces of numerous freshly removed carcinomata. Cultures were also obtained on fuscus crispus after 6 or 8 days, but nothing was learned from them. The bodies closely resembled those described by the botanists, Woronin and Nawaschin, as the cause of parasitic tumor growths in plants. They were large epithelium-like cells, usually showing two large nuclei and clear vacuole-like areas in the center of which was a point which took a bright red stain. They were often found in the interior of lymphoid cells in lymph-glands in the neighborhood of a carcinomatous growth. When found free in exudates they showed distinct amoeboid movement, and their structure was that of amoebae. Leyden believes that carcinoma is probably due to a protozoan infection—and these bodies are probably protozoa. Further statements concerning their relation to the etiology of carcinoma he is apparently unwilling to make.

[D. L. E.]

2.—Previously abstracted from *Deutsch. Med. Woch.*

3.—Two well-developed and apparently healthy men were admitted to the hospital with signs of poisoning. Both worked in an India-rubber factory. It was learned that in the manufacture of india-rubber goods benzine was used, and the patients had been exposed to the vapor of this substance in their work. Acute benzine poisoning is known to occur, but chronic poisoning is not described. In order to determine that the symptoms observed were actually due to benzine poisoning, Dorendorf placed animals in a bell-jar into which air and benzine vapor were passed. These animals showed symptoms closely resembling those seen in the men. Other persons who had been working in the rubber factory for various lengths of time were also found to have more or less marked symptoms. The symptoms were first more or less marked disturbance of the digestive tract, and afterward striking nervous symptoms of a somewhat hysterical type—irregular pains in various parts, paresthesias, reduction in muscular power in one or more extremities, chiefly the anus, increase of knee-jerks, pain on pressure over certain nerves, particularly the radials, nystagmus, tremor of the hands and tongue. There was also a striking blood change in the men and animals. The hemoglobin showed no change in amount or in spectroscopic reactions, and the red cells were not reduced, but granules of pigments of ochre to black color were found in large numbers in the plasma, in the red blood cells and in occasional leukocytes. The animals experimented upon showed toxic changes in the ganglion cells.

4.—The case reported occurred in a woman who had long been a subject of tuberculosis, and died from tuberculosis while her amyotrophic lateral sclerosis was well developed, but not so far advanced as to have had anything to do with her death directly. The brain, cerebral ganglia, and spinal cord were examined microscopically by the Nissl, Marchi, Weigert-Pal and van Gieson methods. They found primary atrophy of the posterior columns and primary degeneration of the lateral columns together, the differential points in these two conditions being: In the first, simple thinning of the fibers, demonstrable only by weight, with thickening of the glia and sclerosis of the vessels, but complete absence of fatty degeneration. While in the second instance there was degeneration of the nerve sheaths easily demonstrable by Marchi, as well as by weight, slight increase of glia, very few round cells in or about the vessel

walls, and many fatty degenerated cells. The change in the vessels is of uncertain importance, as it has not previously been described. The author reviews the literature at length. They consider amyotrophic lateral sclerosis a true system-disease, and agree with Edinger's views that it is in a sense an occupation disease, i. e., that it occurs in those who, by their occupation often in connection with weakened undernourishment or actual weakening diseases, have overtaxed the regions of the central nervous system especially involved. They especially refer to v. Bortol's case in a coachman in which the first signs of the disease appeared in the thenar eminences of the two hands, that is, in the parts which he constantly overtaxed functionally.

5.—Albu's investigations were carried out with an intelligent unmarried woman of 12 as the subject. She stated that she had been using the same diet that she was taking at the time of the experiment for over 6 years; the diet was purely vegetables and fruits without meat, fish or eggs. The average daily ingestion of nitrogen throughout the 5-days' experiment was only 5.46 gm! and the total daily caloric ration was only about 1400, and was only 37.33 to the kilo of body weight. Yet the woman showed a daily nitrogen balance of +0.37 gm., and in 5 days had retained 1.85 gm. nitrogen. It seems evident to Albu from the study of this case that a purely vegetarian diet is capable of maintaining a proper nitrogen balance, and apparently of keeping a person in generally good health. But, as he justly says, to argue from this that a vegetable diet is a thing to be recommended is ridiculous. Meat and eggs would furnish the same amount of nitrogen and of calories in much smaller bulk and in much more digestible form. There is absolutely no scientific objection to be offered to meats and eggs and other animal diets, and therefore to use vegetables exclusively is merely to overtax the digestive organs and to weary the palate, even though metabolism is properly maintained. The most interesting result of the experiment was the observation of a positive nitrogen balance with a ration of only 5.46 gm. nitrogen in the day, and only 37.33 calories to the kilo. These are the lowest figures yet obtained. Siven's subject was getting only 4.52 gms. of nitrogen and only 0.08 gm. to the kilo, and a subject of Paschal's and two of Klemperer got the same nitrogen ration per kilo, but these subjects were all getting much higher total rations, i. e., from 41.4 to 78.4 calories per kilo. Evidently the minimum possible nitrogen ration and caloric ration is not yet determined.

6.—The main purpose of Svenson's investigations was to determine whether the rapid gain in tissues and weight in convalescence which is so commonly observed is due purely to increased intake of food or to a reduction of the metabolic processes similar to that seen with chronically imperfect nourishment. It is known that even with normal or with rather small quantities of nitrogenous food convalescents tend to retain nitrogen and build up nitrogenous tissues. This is of itself not a distinction, however, as the ether foods may be so increased that the nitrogenous foods are spared and the amount of caloric units in food consumed during the day may remain very high. Svenson attacked the question at the end point, making determinations of the respiratory gas-interchange. In convalescence from typhoid fever he found a reduction of the respiratory quotient in the early stages, but the quotient soon increased with a marked increase in the values for oxygen and CO₂, and often a quotient of over 1.0 was found. Similar conditions, though less marked, were found in convalescence from pneumonia. The quotient very gradually decreases to the normal. Nitrogen, he finds, is retained in amounts even under no other circumstances, a fact often observed by other investigators. There may be absorption of large edematous or other exudates in convalescence, however, which may give rise to so large a nitrogen output as to make an apparent nitrogen balance or even an apparent loss. The increase in consumption of oxygen after muscular exercise was abnormally great in convalescence from typhoid fever, but about normal in convalescence from pneumonia. Any intercurrent affection during convalescence is likely to make conditions return to those of an earlier period of the disease itself or of convalescence. In the main the result of the investigation was to disclose the startling fact that convalescents demand and use much more food-energy than in normal persons, and the tissue increase is not the result of economy in metabolic processes,

but of increased intake of food, and if the normal person consumed as much food he would be increased still more in weight than the convalescent does. In a case of carcinoma, the ordinary processes were found at a high normal point or above it. In a case of tetanus, contrary to expectations, the oxidative processes were not increased notably, and at several examinations not at all. [D. L. E.]

7.—Tobiesen carries out the Widal reaction in watch-glasses, observing both by the naked eye and with the microscope. In 350 cases of typhoid fever he got 329 positive reactions with a dilution of 1 to 50. 17 with a dilution of 1 to 10 or 1 to 25. Two cases reacted with 1 to 5 dilution and 2 not at all. 151 cases not typhoid gave 4 positive reactions at 1 to 25 and 25 reactions at 1 to 10. 122 were always negative. The reaction was positive in typhoid during the first week in 138 of 290 cases. Tobiesen examined 20 patients who had typhoid fever from 1 to 23 years previously. All gave the reaction from 1 to 10, but only one gave it as high as 1 to 25, when as much as one year had passed since the attack. Several gave it at 1 to 25 after a year, and one at 1 to 50. Nine of these patients had been examined during the attack and had reacted then at from 1 to 200 to 1 to 700. Evidently the agglutinating power rapidly decreased after the attack. Tobiesen considers the reaction a very important aid in diagnosis, though not always distinctive. Any result is always valueless with a dilution of less than 1 to 50.
